Oscillometric recordings were made at the ankle of many patients. Readings made prior to injection gave an average excursion of 1.5, with a range from 0.5 to 2.5. Post-block recordings in all patients were increased. The excursions varied from 4.0 to 9.0 with an average reading of 5.0. Thus, there was an average increase of 3.5 over the preblock measurements.

Of unusual significance were the observations on 3 patients with spasm, tenderness and pain, and these cases are therefore presented in detail.

CASE 1 A 25-year-old Army nurse contracted poliomyelitis in the Philippine Islands in February, 1946, with paresis of the hamstring, gastrocnemius and soleus muscles bilaterally. She was transferred to the Army and Navy General Hospital in April, 1946. Her chief complaint on arrival was not the paresis but the severe pain, tenderness and muscle spasm involving the hamstring, gastrocnemius and soleus muscles. Because of the slight edema, dusky coloration and coldness of the feet paravertebral sympathetic lumbar blocks were performed. Following the first block on May 29 there was temporary relief of the vasospastic phenomena on the more affected side, but there was complete relief of the pain and muscle spasm lasting for 20 days, whereas on the unblocked side the symptoms were still marked. Subsequent blocks of both right and left sympathetic ganglions resulted in complete relief. This relief persisted, and the patient was sent home on convalescent leave on July 25.

CASE 2 A 20-year-old soldier contracted anterior poliomyelitis on April 16, 1946, while on shipboard returning to the United States from the Philippines. The chief manifestations were in the shoulder girdle, with particular involvement of the deltoid and triceps muscles. Later, weakness of the lower muscle groups, especially the quadriceps, developed. The patient was at first treated with hot packs and passive exercises. He was transferred to the Army and Navy General Hospital on May 30.

On June 4 tenderness and spasm were present in the biceps and triceps muscles of the right side. Stellate-ganglion block performed on the right resulted in an intense Horner's syndrome, the right arm and hand became dry and hot. Subsequent to the block the patient was amazed at the new and improved feeling in the right arm. He stated, "My right arm is now better than my left." Objectively, there was absence of tenderness and no detectable spasm. A second block was performed 2 days later, and the improved state had continued at this writing.

CASE 3 A 32-year-old staff sergeant contracted poliomyelitis on July 9, 1946, in Louisiana. He was transferred to the hospital on July 25. Physical examination revealed bilateral lower-extremity paresis, complete on the right and partial on the left. The chief complaint at that time was extreme pain, tenderness and muscle spasm that kept the patient awake at night. The right lumbar sympathetic ganglions were blocked on July 29, and there was subsequently little tenderness or pain. For the first time since the onset of the illness the patient had a good night's sleep and did not require analgesics. A second block 2 days later re-

sulted in further improvement. Hot packs had been used initially, but only the expected mild comfort was obtained, whereas following the blocks improvement was sharp and definite.

DISCUSSION

The cause of vasomotor disturbances in poliomyelitis has not been completely explained. The intensity of such disturbances is variable, and although a patient may have extensive paralysis, the vasomotor changes do not necessarily parallel the paralysis. Neuropathologically, there is involvement of the intermediolateral cell columns whence the efferent preganglionic fibers arise to pass by way of white rami communicantes to the sympathetic trunk and ganglions. The postganglionic fibers passing via the gray rami are distributed to the vascular system. By alteration in the blood supply to a region the trophic state of the tissues and their metabolism can be influenced. In view of this, Harris⁴ performed sympathectomy with the purpose of promoting the blood supply thereby accelerating bone growth. He noted that sympathectomy resulted in a warm, dry, pink extremity and also that bone growth was apparently enhanced.

In 1933 Ogilvie⁵ reported on sympathectomy for the treatment of vasomotor and sudomotor disturbances in poliomyelitis. In 4 cases lumbar sympathectomy resulted in warm, dry and pink extremities, but this state was only temporary.

In 1934 Robertson⁶ reported on the use of sympathectomy in 68 children with poliomyelitis in the chronic stage. The immediate results were good in the majority of cases, and although a long follow-up period was not possible in every case, several patients had warm, dry and pink extremities at the end of five years.

In the present series of cases with treatment by chemical sympathectomy the results were encouraging (Table 1). Several patients followed for six months after the course of blocks demonstrated continued relief. It is believed that if there is a severe recurrence of vasomotor disturbance, further blocks will be beneficial, and the patients have been so advised. Because of these encouraging results in adults, the question of sympathetic nerve block in children arises. From the standpoint of the anesthesiologist complete co-operation on the part of the patient is needed for successful regional block procedures. This is difficult to obtain in children, but the results in adults are considered to warrant a trial in children, and it is recommended that the cases be selected carefully and attention paid to good premedication.

The problem of treatment of muscle spasm also deserves further investigation. Most textbooks state that muscle spasm subsides in four to eight weeks, but experience with over 130 adult patients with poliomyelitis indicates that spasm and muscle tenderness may persist for several months, and these cases are not exceptional. Hansson and Straub⁷ reported

these cases, however, lacked ocular involvement. The authors suggested that Vincent's infection, associated with altered tissue sensitivity, is an etiologic factor in Stevens-Johnson disease. Oral smears in typical cases, however, have not shown the organism of that infection.

The blood picture is not characteristic. The white-cell count is usually normal or slightly elevated. The case reported above is the first to show a persistent leukopenia. It is interesting to note that in over half the reported cases, the skin eruption is described as hemorrhagic or purpuric at some time during the illness. The purpuric char-

acter may necessitate parenteral feedings for several days. Involvement of the mucous membrane of the genitalia has been reported in approximately a fourth of the cases. The electrocardiographic changes are probably nonspecific and due to the prolonged febrile illness. Edgar and Syvertson¹⁵ reported auriculoventricular block, with changes in the ST segments, in a twelve-year-old patient.

Recurrences of the disease are not rare. In 1 of Edgar's cases, complete relapses occurred six months and eleven months after discharge.

There is no specific therapy for the condition. Penicillin administration to combat secondary in-

FIGURE 2 Photograph Showing the Generalized Eruption

acter of the lesions, which was prominent in the case presented above, is believed to have been associated with the thrombocytopenia. The possibility that low platelet counts existed in similar cases with purpuric tendencies should be considered, although no previous platelet studies have been reported. The patient in the case reported above received sulfadiazine during the seventy-two hours prior to admission, thrombopenia and leukopenia resulting from this medication are a remote possibility. The eosinophil count of 6 to 12 per cent is unexplained. In 3 other cases a moderate eosinophilia was reported.^{15 18 23}

Two fatal cases have been reported in which the syndrome was associated with severe respiratory infections.²⁴ Serious ocular sequelae have frequently been reported. Corneal ulceration with opacification may result, and perforation of the globe with enophthalmus and panophthalmus is not infrequent.¹¹ This has necessitated enucleation in several cases. The stomatitis is usually vesicular or ulcerative, and the membrane sloughs, leaving a raw buccal and palatal surface. The severity of the stomatitis

together with general supportive care, has given the best therapeutic results.

Several cumbersome names have been used to describe this entity, many cases being reported under the titles, "erythema multiforme bullosum with involvement of the mucous membranes," "mucosal respiratory syndrome" and "erythema multiforme plurionficialis." Some observers maintain that the mucosal involvement is simply a symptom of erythema multiforme and that the syndrome should not be considered a distinct entity. Weisberg and Rosen²⁷ have championed this view. Since it is the enanthem rather than the exanthem that seems to be striking, regarding the disease simply as a symptom of erythema multiforme does not stress the more important features. Regardless of the name used, the recognition of the syndrome in its own right is essential.

SUMMARY

A review of the classic cases of erythema multiforme with mucous-membrane involvement (Stevens-Johnson disease) is presented.

There was no history of allergy. The family history was noncontributory.

Physical examination disclosed a patient who appeared acutely ill and shielded the eyes from the light. The skin of both the upper and lower extremities and the trunk was covered with a maculopapular violaceous rash, each lesion had a discrete, rounded border and measured 5 to 20 mm in diameter. Many of the lesions were vesicular, whereas others had a heavy hemorrhagic crust. The intervening skin appeared normal. The palpebral and bulbar conjunctivas were swollen and acutely inflamed, there was a copious purulent conjunctival discharge. The corneas were clear. The anterior nares were reddened and crusted. The lips and the oral mucous membrane were swollen and injected with several denuded and hemorrhagic lesions. The tongue was not involved. The skin about the glans penis was reddened,

FIGURE 1 Photograph on Admission, Showing the Swollen Lids, Encrusted Lips and Erythematous Eruption

and a thick, yellowish exudate was present about the corona and urethral opening. The cervical and axillary lymph nodes were enlarged. The spleen was not palpable.

The rectal temperature was 102.2°F, and the pulse 128. Examination of the blood showed a hemoglobin of 66 per cent and a white-cell count of 4350, with 30 per cent adult neutrophils, 18 per cent young forms, 12 per cent eosinophils, 26 per cent lymphocytes, 8 per cent monocytes and 4 per cent myelocytes. The platelet count was 40,000 by the Rees and Ecker method (normal, over 200,000). Examination of the urine revealed occasional white cells in the sediment. The stools were normal. The blood sulfadiazine level was 2.1 mg per 100 cc. The prothrombin time was normal, as were the coagulation and bleeding times. Clot retraction was complete in 12 hours, and the clot was of fair quality. A Rumpel-Leede test was strongly positive. Agglutination tests for typhoid, paratyphoid and typhus fevers, brucella, infectious mononucleosis and tularemia were negative, as were nasopharyngeal, throat, blood and conjunctival cultures.

During the first 3 days, the conjunctivas were irrigated with boric acid solution, and general supportive care was given, including intravenous fluids and blood transfusions. The conjunctivitis became severer, and pseudodiphtheritic membranes covered the corneas and scleras. These membranes were easily removed with forceps, and the underlying

corneas were clear. Conjunctival culture on the 4th hospital day showed only colonies of hemolytic *Staphylococcus aureus*, and 10,000 units of intramuscular penicillin every 3 hours was begun, penicillin ophthalmic ointment being applied locally. The protective membranes gradually sloughed away during the 2nd week, and both corneas revealed ulcerations that subsequently underwent opacification. By that time, the skin eruption had taken on a purpuric character that was believed to be associated with the thrombopenia (counts of 40,000 to 80,000 platelets). Most of the skin lesions became vesiculated and then ruptured, yielding a clear fluid, after which the layers of skin became adherent and hemorrhagic crusts covered the lesions. The oral mucosa underwent vesicle formation and sloughed, leaving raw areas that bled easily. Cultures of the skin vesicles were repeatedly negative. A light growth of hemolytic *Staph. aureus* was occasionally cultured from the oral lesions. On the 4th day, the spleen was felt to be enlarged. The white-cell count remained below 5000 during the first 2 weeks, and an eosinophil count of 6 to 12 per cent persisted during that time. Stool examinations for parasites were negative. The balanitis had subsided completely by the end of the 2nd week. The crust over the skin began desquamating during the 2nd week, and by the 3rd week, the skin revealed only dark brown patches of pigmentation at the site of the former lesions. The oral mucosa began re-epithelializing and was completely healed by the 3rd week. The platelet counts remained below 100,000 for the most part. Clot retraction and clot quality were impaired in proportion to the thrombocytopenia. An electrocardiogram showed prominent Q waves in the limb leads, with a PR interval of 0.18 second.

The patient was observed for 11 weeks. During that time the skin pigmentation slowly faded. The corneal opacities cleared slightly. The initial course of penicillin was continued through the 11th day and then stopped for 9 days. Penicillin was resumed intramuscularly on the 20th day because of corneal ulceration and continued for 5 weeks. The temperature gradually fell to normal on the 4th day and remained normal during the hospital course. Shortly before discharge the patient developed acute pharyngitis, which cleared rapidly. He was discharged without symptoms, except for slight photophobia and impaired vision, on the 75th hospital day.

On follow up in the ensuing 11 months, the skin pigmentation had gradually faded. The corneal opacities that had encroached on the central vision had remained at about the same density and necessitated placing of the child in a sight-saving class. Visual acuity on July 10, 1946, showed 20/60 bilaterally. Several small adhesions of the palpebral and bulbar conjunctivas remained but did not restrict motility. The platelet counts were normal. The child was in perfect health except for the visual defect.

Although Stevens-Johnson disease has been considered primarily pediatric, approximately a third of the cases reported since 1922 have occurred in patients over fifteen years of age,⁸⁻¹⁰ the case reported by Jones et al.²² having occurred in a fifty-six-year-old woman. The sex incidence is five to one in favor of male patients.

No known etiology for the disease has been established. A virus has been suggested, but no virus has been isolated. Jones and his associates²² examined conjunctival and vaginal scrapings and found no virus inclusion bodies. Their complement-fixation studies of patients' blood with psittacosis antigen showed positive values in dilutions only up to 1:64. Givner and Ageloff¹⁹ found no inclusion bodies in vesicular fluid from skin lesions. Cultures on chick embryos were also negative. Edgar and Syverton¹⁶ injected vesicular fluid intracerebrally and intraperitoneally in rabbits, guinea pigs and mice, with no effects. Chick and Witzberger¹² reported a case and referred to 2 others of Vincent's stomatitis accompanied by erythema multiforme,

MEDICAL PROGRESS

STREPTOMYCIN*

I Bacteriologic and Pharmacologic Aspects

RODERICK MURRAY, M.D.,† TOM F. PAINE, M.D. ‡ AND MAXWELL FINLAND, M.D. §

BOSTON

SEVERAL months have elapsed since streptomycin became available in this country for use in hospitals and then to physicians generally. Heralded at first as the final fruit of victory in the battle against bacterial infections, it seemed to be the obvious and natural supplement to penicillin and was to fill the few gaps among the infections that could not be disposed of by that potent agent. Experiences with penicillin, however, had conditioned the practitioner to expect from streptomycin brilliant, rapid and consistent results in susceptible infections and with essentially no untoward effects.

It soon became apparent, however, that none of these expectations would be entirely fulfilled and that considerable disappointment was inevitable. Streptomycin has, nevertheless, proved to be a useful agent, if properly employed, in certain types of infections. It seems desirable, therefore, to review the available information concerning this antibiotic and to define, so far as that information permits, its field of usefulness and its limitations. The first part of this progress report deals with the properties of streptomycin, its pharmacology and its effect on bacteria in vitro and in experimental infections in animals. The results of its clinical uses in various infections will be considered in the second part.

DISCOVERY AND DEVELOPMENT

Streptomycin is the product of a search by Waksman and his associates^{1, 2} for antagonistic organisms that are active against gram-negative bacteria. Certain actinomycetes, most of them isolated from soils or composts, were found to produce substances possessing marked antibacterial properties, but few of them offered chemotherapeutic potentialities. The first antibiotic that looked promising for the treatment of infections with gram-negative bacteria was streptothricin,^{3, 4} which was active both in vitro

and in vivo. Purified preparations of this substance, however, exerted a delayed toxic effect in animals and, in addition, certain important gram-negative bacilli were found to be naturally resistant to high concentrations.

At the same time, a search was also under way for antibiotics active against acid-fast bacilli. Certain fungi, notably *Aspergillus fumigatus*, were found capable of suppressing the growth of *Mycobacterium tuberculosis*.⁵ Similar groups of organisms were therefore investigated. These combined studies resulted in the isolation of a strain of actinomyces from a heavily manured soil that was similar to one that Waksman had isolated in 1919 and had then classified under the name *Actinomyces griseus*.¹ The antibiotic, produced by the freshly isolated strain in a medium containing meat extract, resembled streptothricin in many respects but differed from the latter in that it had much greater activity against a number of pathogenic gram-negative bacteria and was free of many of its toxic effects in animals. The substance was called streptomycin, the name being derived from the generic designation given to the sporulating and aerial-mycelium producing group of actinomycetes — namely, the Streptomyces.⁶

Other antibiotics have been extracted from *Streptomyces griseus*.⁷⁻¹⁰ One of them has antifungal activity,^{7, 8} and another, called "grisein," has no antifungal properties and a narrower bacterial spectrum than streptomycin.⁹

Only certain strains of *Streptomyces griseus*, however, produce streptomycin.⁹ The composition of the medium is also important.² Among other things, certain organic constituents supplied by the meat extract seem essential, but these can also be supplied by corn steep liquor and some other substances.^{2, 10, 11} Aerated cultures produce maximum growth more rapidly than stationary ones. The medium becomes alkaline during the growth. Growth is terminated at the stage of maximum streptomycin production. The organisms are removed, and the antibiotic is extracted from the clear medium by adsorption on active charcoal. It is then eluted and extracted with suitable solvents and finally concentrated by desiccation in vacuo.² Further treatment is necessary to obtain the pure crystalline product, which is a white powder.^{2, 11, 12}

A number of contributions may have been overlooked or may not have been available at the time of this writing and many more have appeared since this paper was completed and therefore could not be included.

A case with an erythematous skin eruption, associated with fever, a purulent conjunctivitis, severe stomatitis and balanitis is reported. Corneal ulceration with opacification was the only sequela. The course and clinical picture were almost identical with those in the cases described by Stevens and Johnson.

Persistent leukopenia and thrombocytopenia are reported for the first time in this syndrome.

in the assay broth to act as an indicator of bacterial growth. Some authors have advocated the use of the least enriched medium that will give adequate growth.⁵¹

Slide-cell method⁵² The action of streptomycin is observed microscopically by its inhibition of growth of *B. megatherium* in defibrinated blood.

Turbidimetric method Electrophotometric measurement of the turbidity of a staphylococcus culture containing streptomycin has also been used as a basis for assay.⁵⁴

The results of these assays depend not only on variations in the methods used but also on such factors as the type and nutritive value of the medium,^{41 55-55} the salt concentration,^{46 55 59} the hydrogen ion concentration,^{34 46 60 61} the test organism,^{35, 42-45, 49-52} aerobic conditions,³⁶ the size of the inoculum,^{47, 48 60, 62} the time of incubation^{57 62} and factors that inhibit the test organism and are present in the medium^{2 34 37 49 55 56} or in the material being assayed^{49 53 55 63 64}. This last factor may be quite important when *B. subtilis* is used, since it has been shown that a large proportion of human serums inhibit the growth of *B. subtilis* in varying degrees.⁶⁵ This effect may possibly be minimized by the use of citrated plasma instead of serum as in penicillin assay.⁶⁶ Uniform assay mediums have been proposed^{45 49} and are marketed, but their use is by no means universal.

Chemical methods of assay,^{23 67 68} based on the properties of streptomycin or of its degradation products and not necessarily related to antibiotic activity, may have technical usefulness. For the present, however, biologic methods are the most satisfactory for clinical use.

ABSORPTION, EXCRETION AND DISTRIBUTION

Absorption

Blood levels following intravenous and intramuscular administration of streptomycin have been extensively studied in man^{44 45 69-75} and in animals^{47 76-78}. In general, maximum levels are attained a few minutes after intravenous injection, whereas after intramuscular injection of the same dose there is a gradual rise to a maximum in one or two hours.^{69 72 73} At that time the levels are approximately the same for either method of administration, and there is a gradual falling off, with some evidence that the levels from the intramuscular injections are somewhat better sustained.^{72, 73} The levels attained and the duration of detectable activity in the blood serum depend on the size of the dose, but are not directly proportional to it.⁷² Table 1 shows serum levels attained at different times after various doses. These figures agree in the main with those reported by others, most of whom used similar assay methods — variations of the technic described by Stebbins and Robinson.⁴²

Subcutaneous injections have not been widely used in human beings, but levels may be obtained

that are only slightly lower than those following intramuscular administration.^{69 71, 73} Measurable levels of streptomycin may still be present in the blood twelve hours after a single injection of 200,000 units,⁷³ but therapeutic levels cannot be relied on after six hours in a normal subject.

Intermittent injections of suitable doses by any of these three parenteral routes every four to six hours will ensure the maintenance of desired levels. There may be some build up of levels after the first

TABLE 1 Serum Concentrations in Man after Various Doses of Streptomycin *

Dose units	TIME AFTER INTRAVENOUS OR INTRAMUSCULAR DOSE		
	1 hr	2 hr	4 hr
2,000-50,000	1-5-2-5	1-0-2-5	0
200,000	10	6	3
400,000	10-15	8	6
500,000	15-20	15-20	10-15
1,000,000	25-50	25-45	15-25

*From Buggs et al.⁷²

few successive injections.^{69 70 72} An attempt to slow absorption from intramuscular injections by the use of streptomycin in beeswax and peanut oil or Solvecillin (a water-in-oil emulsion) gave inconclusive results.⁷⁹

When streptomycin is given orally only small amounts appear in the blood and urine.^{44, 45 47, 69-71, 72 78} The fecal concentration after oral administration is high,^{44 69} and almost all the administered streptomycin is recoverable in the feces, indicating that failure to enter the blood stream from the gastrointestinal tract is due to poor absorption rather than to destruction.⁴⁵ Artificial gastric or duodenal juice does not inactivate streptomycin.⁷⁰

An appreciable concentration of streptomycin is still present in the cerebrospinal fluid twenty-four hours after an intrathecal injection of 20,000 units.⁷⁰ Similar results have been obtained by many workers.^{71 72 80 81}

Few reports are available on the absorption of streptomycin given as an aerosol. Detectable amounts are not present in venous blood, and only small amounts are found in the urine after inhalation of 200,000 units or less.^{71 73 82} In a patient receiving 500,000 units daily, 6 per cent of the administered dose was found in the twenty-hour urine.⁷¹

Excretion

The bulk of the streptomycin excreted following parenteral administration is found in the urine, only a small fraction — 6 per cent or less — being found in the stools.^{45 69} Streptomycin has been recovered as an active colorless solid from the urine of dogs, according to Tennant, cited by Robinson.⁸³ Excretion in the urine is greatest during the two hours following a single intravenous or intramuscular

CHEMICAL PROPERTIES

ASSAY

Streptomycin was early recognized to be an organic base.² Crystalline reineckates were soon obtained, and tentative empirical formulas were derived from analyses of these salts.¹⁴⁻¹⁶ Some studies of its structure have shown that it is composed of two main portions¹⁷⁻²¹ streptidine ($C_8H_{14}O_4N_6$), a basic substance, and streptobiosamine ($C_{13}H_{21-23}O_5N$), a nitrogen-containing disaccharide to which streptidine is joined through a glucoside linkage, which is readily split by methanolic hydrochloric acid.¹⁷ Further information concerning the composition and structure of streptidine^{18, 20-22} and the degradation products of streptobiosamine²²⁻²⁵ has been revealed, but the final elucidation of the structure of streptomycin and its synthesis remains to be accomplished.

Streptomycin is a hygroscopic, optically active,¹² organic base, soluble in water but insoluble in the usual organic solvents. It forms salts with acids, and of these the soluble hydrochloride and sulfate are used clinically. The relatively insoluble helianthate is used in some methods of purification,¹² and the crystalline reineckate has been utilized for its characterization.¹⁴ It is adsorbed on charcoal in alkali and may be eluted by acid.^{2, 26, 27}

Streptomycin reacts with a number of carbonyl reagents.¹⁷ It is readily oxidized to inactive streptomycinic acid by bromine.²² Catalytic reduction by hydrogen results in dihydrostreptomycin,²⁸⁻³⁰ which is a substance having antibiotic activity of the same order as streptomycin but which, in contrast to it, does not lose activity in the presence of cysteine or carbonyl reagents and is also stable at a higher hydrogen ion concentration.²⁹ Streptomycin reacts with alkaline copper solutions, urines containing 1000 units or more reduce Benedict's solution.³¹

STABILITY

Streptomycin is a relatively stable substance. Commercial samples containing less than 1 per cent of moisture show no loss of potency when stored at room temperature for a year.³² It is also stable in solution at ordinary temperatures, there is no loss of activity in solutions at or below 28°C at pH 3 to 7 over a period of sixty days, whereas it requires thirty-seven hours at 95°C to reduce the activity of a solution at pH 5.5 to a half.³² Buffered solutions containing 100 and 1000 units per cubic centimeter at pH 6.0, 7.0 and 8.0 are stable over a period of three months at 10°C.³³ Heating at 70°C for thirty minutes produces no appreciable loss of activity.^{34, 35} Less than 50 per cent loss occurs on heating at 100°C for 10 minutes.³ A marked increase in alkalinity causes rapid destruction, and boiling with normal sodium hydroxide for ten minutes results in complete inactivation.³³ No biologic agent or enzyme system has yet been found capable of destroying streptomycin.³⁶

Units

Amounts of streptomycin are now expressed in terms of the weight of the pure base in grams, milligrams or micrograms.³⁷ Waksman³⁸ originally measured streptomycin in units, the unit being defined as the minimal amount of streptomycin activity that must be present in 10 cc of nutrient medium to inhibit the growth of a given strain of *Escherichia coli*, this has also been called the "*Esch coli* unit" or "S unit," which is approximately equivalent to 10 microgm.* He also proposed two other units: an "L unit," to indicate 1,000,000 S units, and a "G unit," to represent 1000 S units. These designations are no longer widely used. Commercial streptomycin is provided as the hydrochloride or sulfate, but the potency is expressed in terms of the weight of the pure base.⁴⁰

Methods

Procedures that depend on the antibacterial properties of streptomycin have been widely used and form the basis of all the reported quantitative studies in patients. Most of them employ the same principles that are used in penicillin assay, with variations in the mediums and test organisms to suit the properties of streptomycin.

Streak-plate method.⁴¹ This is a crude method that consists in the incorporation of graded dilutions of the material being tested in nutrient agar, followed by streaking of the surface with an array of organisms of known and graded sensitivity.

Agar-diffusion methods. These are modifications of the cylinder-plate technique⁴² described for penicillin assay, and two main types are used. The first comprises the cup method, in which the material being assayed is placed in cups arranged on the surface of suitable agar plates seeded with a test organism. Stebbins and Robinson⁴³ used *Staphylococcus aureus* as the test organism. This procedure has been widely used and modified, and other test organisms — notably *Bacillus subtilis*^{44, 45} — have been proposed. The second is the paper-disk method, which is a further modification of the first type, in which the assay cylinders are replaced by small paper disks moistened with the solutions being assayed.^{46, 47}

Broth-dilution methods. Serial dilutions, usually twofold, are set up as in the penicillin assay method described by Rammelkamp.⁴⁸ The organisms generally used have been strains of *Klebsiella pneumoniae*,⁴⁹⁻⁵¹ *B. circulans*⁵² and *Staph. aureus*,⁵³ and the inoculum is between 1000 and 100,000 organisms per cubic centimeter. End-points have been determined by turbidity or subculture, or both, on nutrient agar with or without inclusion of blood.

*It is well to bear in mind that this unit has no relation to that of penicillin. The original Oxford unit of penicillin was defined as the amount required to inhibit 50 cc of a staphylococcus culture. The international unit of penicillin is now defined as 0.6 microgm of pure penicillin G.⁵⁴

duction of acid³⁶ When a glycine buffer of pH 8 is present, no inactivation occurs Glycine itself has no demonstrable effect on streptomycin³⁶

Effect of aerobic and anaerobic conditions The action of streptomycin on facultative anaerobes is reduced if they are grown in an atmosphere of hydrogen or nitrogen instead of air and is almost completely abolished in carbon dioxide These changes are related to the reaction and are prevented, in carbon dioxide, by the addition of potassium bicarbonate to the agar³⁶

Inactivation by chemical substances The inhibitory and inactivating effect of a number of chemical substances has been studied^{17, 36, 93-96} Cysteine inactivates streptomycin, and this effect is reversible by iodine⁹³ Among other substances tested 2-aminoethanediol caused inactivation⁹³ Thioglycolic acid may also cause inactivation,^{36, 96} but this may be due to the presence of glucose in the thioglycollate medium³⁶ or to an effect on the oxidation-reduction potential⁹⁵ Among oxidizing and reducing agents that have been tested potassium permanganate and potassium periodate were the most effective in destroying the antibiotic activity of streptomycin⁹⁵ Vitamin C⁹⁵ and carbonyl compounds¹⁷ such as hydroxylamine, semicarbazide, phenylhydrazine and methylphenylhydrazine, may reduce its activity About 98 per cent inactivation is attainable at pH 5.5 with semicarbazide, and this substance has been proposed for use in the sterility testing of concentrated streptomycin solutions⁹⁷

Effect of body fluids The action of streptomycin on staphylococci was not appreciably influenced by various body fluids, pus or normal tissue juices⁶¹ Incubation of the drug with artificial gastric or duodenal juice had no appreciable effect on its activity⁷⁰ Defibrinated blood and normal urine, likewise, did not decrease the activity⁵⁸ Some reduction in activity was noted, however, in human serum.⁵⁵ The effect varies with the organism and with the concentration of the serum Serum may enhance the activity of streptomycin against *Escherichia coli*⁶⁴ or *K pneumoniae*,⁴⁹ whereas it inhibits this action against various organisms including *Staph aureus* and *Streptococcus haemolyticus*,^{63, 64} and it does not affect the sensitivity of *Brucella*⁶³ Possibly, these conflicting results are due to differences in the methods used Their clinical significance is not clear

MECHANISM OF ACTION

Streptomycin is generally bacteriostatic for susceptible organisms in low concentrations and bactericidal at higher levels^{2, 93-101} Microscopical examinations of organisms growing in subinhibitory levels of streptomycin have shown morphologic changes¹⁰² Large bizarre forms were noted in the study of *Eberthella typhosa*¹⁰⁴ and *Pasteurella tularensis*,¹⁰⁵ whereas marked elongation was noted with *Shigella sonnei* and to a lesser extent with

Salmonella typhimurium, *Aerobacter aerogenes* and *Proteus ammoniae*¹⁰¹ Streptomycin has a bactericidal action both on growing cultures and on resting or nonmultiplying cells,^{100, 101, 106} although this may not be true of its action on tubercle bacilli¹⁰⁷ This bactericidal action is more marked against young

TABLE 2 Sensitivity of Various Organisms to Streptomycin

ORGANISM*	REPORTED SENSITIVITY RANGE	MOST FREQUENT
<i>Actinomyces visus</i> ¹⁰⁸	0.5-125	6-27
<i>Aerobacter aerogenes</i> ¹⁰¹	0	
<i>Bacillus anthracis</i> ¹⁰⁹	0	
<i>Bacillus cereus</i> ¹¹⁰	0.8-2	
<i>Bacillus megaterium</i> ¹¹¹	0.2-1	
<i>Bacillus subtilis</i> ¹¹²	0.1-125	1-5
<i>Brucella abortus</i> ¹¹³	0.1-1	
<i>Brucella melitensis</i> ¹¹⁴	0.1-1	
<i>Brucella suis</i> ¹¹⁵	0.1-1	
<i>Clostridium perfringens</i> ¹¹⁶	>104	
<i>Clostridium septicum</i> ¹¹⁷	>10	
<i>Clostridium tetani</i> ¹¹⁸	>10	
<i>Clostridium botulinum</i> ¹¹⁹	>104	
<i>Clostridium histolyticum</i> ¹²⁰	>100	
<i>Corynebacterium diphtheriae</i> ¹²¹	0.1-1	
<i>Diphtheria</i> ¹²²	4-50	
<i>Diphtheroides</i> ¹²³	1-125	
<i>Enterobacteriaceae</i> ¹²⁴	1-120	1-16
<i>Escherichia coli</i> ¹²⁵	0.1-1	
<i>Haemophilus ducreyi</i> (chancroid) ¹²⁶	0.1-1	<5
<i>Haemophilus influenzae</i> ¹²⁷	0.1-1	
<i>Haemophilus parainfluenzae</i> (Pleiffer's bacilli) ¹²⁸	1-10	1-5
<i>Haemophilus parvus</i> ¹²⁹	2-5	
<i>Haemophilus pyrus</i> ¹³⁰	1-17	1-
<i>Histoplasma capsulatum</i> ¹³¹	>2500	
<i>Klebsiella pneumoniae</i> ¹³²	0.2-1.5	
<i>Klebsiella terrigena</i> (Friedlander's bacilli) ¹³³	0.2-125	0.6-8
<i>Listeria monocytogenes</i> ¹³⁴	2-5	
<i>Malleomyces mallei</i> (glanders) ¹³⁵	10-100	
<i>Mycobacterium tuberculosis</i> (avian) ¹³⁶	10-50	
<i>Mycobacterium tuberculosis</i> (human and bovine) ¹³⁷	0.1-1	
<i>Nisseria catarrhalis</i> ¹³⁸	1-4	
<i>Nisseria gonorrhoeae</i> (gonococcus) ¹³⁹	5-40	10-15
<i>Nisseria intracellulare</i> (meningococcus) ¹⁴⁰	1-40	
<i>Nocardia</i> ¹⁴¹	4-12.5	
<i>Pasteurella pestis</i> (plague) ¹⁴²	0.5-1.5	
<i>Pasteurella tularensis</i> ¹⁴³	0.1-0.5	
<i>Paracolon bacillus</i> ¹⁴⁴	2-128	2-16
<i>Proteus morganii</i> ¹⁴⁵	1-128	5-50
<i>Proteus vulgaris</i> ¹⁴⁶	0.4-128	4-25
<i>Pseudomonas aeruginosa</i> (Bacillus pyocyaneus) ¹⁴⁷	2-200	8-50
<i>Salmonella</i> (various species) ¹⁴⁸	4-120	4-32
<i>Serratia lutea</i> ¹⁴⁹	0.25	
<i>Serratia marcescens</i> (Bacillus prodigiosus) ¹⁵⁰	1-64	
<i>Shigella</i> (various species) ¹⁵¹	0.2-8	3-7
<i>Staphylococcus albus</i> ¹⁵²	1-256	1-4
<i>Staphylococcus aureus</i> ¹⁵³	0.5-128	1-5
<i>Streptococcus faecalis</i> ¹⁵⁴	12.5-60	
<i>Streptococcus haemolyticus</i> ¹⁵⁵	1-128	2-32
<i>Streptococcus nonhemolyticus</i> ¹⁵⁶	1-128	1-32
<i>Streptococcus mitis</i> ¹⁵⁷	0.1-128	1-12
<i>Streptomyces</i> (various species) ¹⁵⁸	0.4-12.5	
<i>Vibrio cholerae</i> (cholera) ¹⁵⁹	5-100	

* A few additional organisms are listed by Waksman and Schatz¹⁶⁰ and by Pulaski and Sprinz¹⁶¹ Additional fungi are mentioned by Robinson¹⁶² and Reilly¹⁶³

[†] Minimum inhibiting concentration of streptomycin in micrograms per cubic centimeter of culture

cultures than against older ones³⁶ Streptomycin has no effect on tetanus toxin¹⁰³

There is as yet no clear evidence to indicate just how streptomycin acts Some antibiotics are adsorbed on the surface of bacterial cells, but this is apparently not true with streptomycin, at least so far as *B subtilis* and *Staph aureus* are concerned⁹⁵ It has been suggested that streptomycin acts by the combination of its guanido groups with

injection, up to 65 per cent is excreted in twelve hours, and 9 per cent more may appear during the following twelve hours.⁷³ The amount excreted in twenty-four hours is variously estimated as representing 17 to 90 per cent of the administered dose,⁷⁷ with averages of 57 to 66 per cent.⁶⁹ Only negligible amounts are recoverable from the urine after twenty-four hours.⁴⁴ ⁶⁹ ⁷¹ Streptomycin is concentrated by the kidney, and high urine levels are easily attainable with therapeutic doses. The levels depend largely on the volume output of urine and have ranged from 120 to 2000 units per cubic centimeter,⁵⁰ ⁶⁹, ⁷¹ ⁷³ ⁸⁴ ⁸⁵ and even over 4000 units per cubic centimeter have been reported.³¹, ⁸⁶ The renal clearance of streptomycin has been studied, and the drug was found to be excreted by the glomeruli alone, 38 to 67 cc of plasma being cleared per minute.⁷² There may be diminished excretion and consequent concentration in the blood in patients with severe renal damage.³¹, ⁷², ⁸⁶

Distribution

Following parenteral injection streptomycin is found in most of the body fluids and tissues. Concentrations are higher in the kidney than in the blood.⁵⁸ ⁷³ The findings in other organs are irregular.⁴⁷ ⁵³ ⁷² ⁸⁷ and probably unreliable. In mice, high concentrations are found in the liver and spleen if the streptomycin is given with trypan blue.⁸⁷ No demonstrable streptomycin was present in red cells hemolyzed by freezing, although the plasma removed from the same sample of blood showed a good level.⁷² Streptomycin was not found in pus from soft-tissue abscesses in 4 cases.⁵³

Spinal fluid Most authors failed to demonstrate significant amounts of streptomycin in the cerebrospinal fluid even after large intravenous or intramuscular doses, when there was no meningeal inflammation,⁶⁹ ⁷¹⁻⁷³ although 1 to 5 units per cubic centimeter may be found in the cerebrospinal fluid of patients with meningitis following similar injections.⁶⁹⁻⁷³

Pleural fluid Levels found in the pleural fluid of patients with effusions, although somewhat lower,⁵³ may be better sustained than those attained in the blood.⁶⁹ ⁷³ The appearance of streptomycin in pleural fluid is apparently slower if the fluid is thick.

Peritoneal fluid The drug is found in the peritoneal fluid following parenteral administration, and the concentrations are usually less than those in the blood.⁵³ ⁶⁹ ⁷² ⁷³ Whereas most of the studies were made on patients with ascites, it has been shown that the agent readily enters the peritoneal fluid of normal dogs and of dogs with acute diffuse peritonitis.⁸⁸ Doses of 500,000 to 600,000 units intravenously or intramuscularly result in peak levels of 15 to 33 units per cubic centimeter.⁸³

Bile Numerous studies have been made on the presence of streptomycin in bile.⁵³ ⁶⁹ ⁷¹ ⁷³ ⁸⁹ ⁹⁰ The drug was found in the bile only when the

cystic duct was patent. It does not seem to be concentrated by the liver, and levels in the bile are lower than those found in the blood. Impaired liver function results in lower levels or even absence of streptomycin in the bile. There is no evidence of absorption or concentration in the gall bladder.

Ocular fluids In rabbits, good levels were readily achieved in the conjunctiva, sclera, extraocular muscles and aqueous humor following intravenous administration. Higher concentrations were attainable in secondary aqueous. Penetration to the aqueous was not accomplished by local instillations unless the cornea was damaged. High concentrations could be obtained by iontophoresis.⁹¹ In a case of glaucoma⁸⁹ the secondary aqueous showed higher levels than the aqueous.

Fetal blood and amniotic fluid Streptomycin readily passes through the placenta and is found in the fetal circulation.⁷¹ Levels in umbilical-cord blood and amniotic fluid were approximately half those found in the maternal blood taken at the same time. Only negligible amounts were detected three hours after injection of the mother.⁹²

FACTORS INFLUENCING ACTION OF STREPTOMYCIN IN VITRO

Effect of reaction and number of organisms The antibiotic effect of streptomycin is greater in an alkaline than in an acid medium.³¹ ⁴⁶ ⁶⁰ ⁶¹ In addition, streptomycin activity is considerably decreased if the size of the inoculum is sufficiently increased.⁵⁷ ⁵⁸ ⁶⁰ ⁶² With an inoculum of 5000 or 10,000 organisms per cubic centimeter there may be a fourfold loss of activity with a change in reaction from pH 7.2 (at which activity is usually estimated) to pH 6.2 (a fairly usual reaction for pus). If, in addition, the inoculum is increased a thousandfold, the same change in reaction will decrease the activity sixteen to thirty-two times.⁶⁰ The effect of acidity is not due to destruction of streptomycin, since it can be restored by upward adjustment of the reaction.⁶¹ These two factors may have contributed to some of the failures of streptomycin, as in cases of walled-off collections of pus.⁷⁴

Effect of salts The addition of many salts, such as sodium chloride, acetate and bicarbonate, potassium chloride and bicarbonate, lithium chloride and sulfate and some phosphates, has been found to increase the effect of streptomycin against *B. subtilis*.⁴⁶ Others,⁵⁸ ⁵⁹ however, noted a reduction in effect on certain organisms in the presence of increased salt concentrations, but their observations were made under different conditions. The salts in normal urine did not decrease streptomycin activity.⁵⁵

Effect of glucose Glucose reduces the activity of streptomycin.² ³⁴ ⁶⁶ The potency of streptomycin in agar is reduced to a half in the presence of 2 mg in 10 cc. This effect is probably related to the pro-

Spirochetal infections A considerable therapeutic effect was noted against *Borrelia nocy* (one of the organisms of relapsing fever) in mice and *Leptospira icterohaemorrhagiae* (the etiologic agent in Weil's disease) in Syrian hamsters, the effect in these infections, however, was less than that produced by penicillin.¹⁶⁴ A suppression of the infection in rabbits was caused by the Nichols strain of *Treponema pallidum* after prolonged therapy with large doses (200,000 units a day),¹⁶⁵ ¹⁶⁶ but lower doses failed to suppress the infection.¹⁶⁷ ¹⁶⁸

Fungous infections Streptomycin was ineffective against *Blastomyces dermatitidis* infections of chick embryos.¹⁶⁹

Virus and rickettsial infections Streptomycin failed to affect the multiplication of a number of strains of influenza A and B viruses¹⁷⁰ ¹⁷¹ and the viruses of psittacosis¹⁷⁰ and meningopneumonitis¹⁷¹ in chick embryos. It was ineffective in the prophylaxis and treatment of experimental vaccinia in rabbits.¹⁷² It was more active than penicillin against *Donausia granulomatis* in embyonated eggs.¹⁷² Feline pneumonitis was not suppressed by streptomycin in vitro or in vivo.¹⁷³ In doses of 2 mg per egg it suppressed the growth of the rickettsias of epidemic (louse-borne) and endemic (murine) typhus fever in chick embryos but had no effect against that of scrub typhus fever in the same amounts.¹⁷⁴ It also suppressed the growth of the virus of lymphogranuloma venereum in eggs.¹⁷⁵

Protozoal infections No action was noted against *Plasmodium cathamerum* in canaries¹⁷⁶ or *P. lophurae* in ducks.¹⁷⁷ ¹⁷⁸ A slight suppressive action was noted against *P. gallinacium* in chicks.¹⁷⁹

LABORATORY USES

Streptomycin has been used either alone or in conjunction with penicillin or sulfonamides, or both to prevent contaminations by susceptible organisms in the course of isolation of various infectious agents,¹⁷⁶ ¹⁷⁷ including viruses¹⁷⁶ ¹⁷⁷ and protozoa.¹⁸⁰ ¹⁸¹ It has no effect on the embryo of the developing hen's egg, at least in the concentrations that have been used.¹³⁶ ¹³⁷ ¹⁴⁸ ¹⁷⁶ ¹⁷⁷

TOXICITY IN ANIMALS

A great deal of work has been done concerning the toxicity of streptomycin for animals, most of it by Molitor and his co-workers.³⁷ Administration of the drug produces acute and chronic toxic reactions, some of which deserve special mention.

Acute Toxicity

The toxicity of purified specimens of streptomycin is extremely low.² ³⁷ ¹⁰² Acute toxicity in mice was evidenced by increased activity, dyspnea and respiratory failure. The LD₅₀* for mice, determined on two hundred lots of streptomycin, ranged from 350 to 700 mg per kilogram of body weight in

*Smallest amount killing 50 per cent of the animals within the test period.

most cases. Differences in toxicity could not be correlated with the potency of the preparations studied. The LD₅₀ for eight samples of highly purified streptomycin ranged from 75 to 300 mg per kilogram of body weight when given intravenously and from 300 to 1250 mg when given subcutaneously — a ratio of about 4:1. The LD₅₀ for guinea pigs was 400 mg per kilogram of body weight for a batch whose LD₅₀ for mice was 600 mg.³⁷ Similar values in guinea pigs have been obtained by others.¹⁶¹ Subcutaneous injection of 30 to 70 mg per kilogram of body weight produced acute respiratory distress in monkeys.³⁷ Mice survived oral administration of 5000 mg of pure streptomycin per kilogram of body weight, whereas doses of 1000 to 3000 mg of crude concentrates per kilogram of body weight proved fatal.³⁷

Chronic Toxicity

Mice receiving up to a total of 1000 mg per kilogram of body weight subcutaneously in six days appeared normal, as did rats after seventy-two days on 100 mg daily and guinea pigs on amounts up to 60 mg per day. No pathologic changes were noted in these animals.³⁷ ^{184†}

Rats developed nutritional deficiencies when fed large doses of streptomycin and purified diets for prolonged periods¹⁷⁸ but not with smaller doses¹⁷⁸ or when the diet contained essential growth factors.¹⁷⁹ The picture presented, which was similar to that observed in experimental biotin deficiency, responded to biotin therapy.¹⁷⁸ The bacterial content of the feces of these animals was markedly reduced.

Monkeys given large doses parenterally — 50 to 100 mg per kilogram of body weight — exhibited proteinuria, and some showed bromsulfalein retention. Autopsies revealed a peculiar type of fatty infiltration of the kidneys and less often of the liver. There was evidence that this process is reversible.³⁷ Dogs given 50 to 100 mg showed protein, casts and cells in the urine after one and a half to two weeks. Three of the dogs developed changes in gait and posture suggestive of labyrinthine or cerebellar disturbance,³⁷ a phenomenon that has also been noted in human beings.^{180, 181} No obvious pathological changes were found in the central nervous systems of these dogs.¹⁸²

An investigation of the antidiuretic properties of streptomycin was carried out following a report of urinary retention in man occurring after administration of the drug.¹⁸³ It was shown that this effect was associated with impurities but that pure streptomycin had no such effect.³⁷

Local Effects

Instillation of a solution of streptomycin caused reddening of a rabbit's eye,³⁷ ¹⁸⁴ but this disappeared within twelve to twenty-four hours when the solu-

†Slanetz (Proc Soc Exper Biol & Med 63:451-453, 1946) observed no toxic effects in mice fed up to 1000 mg daily but a greater increase in weight occurred in second litters at higher dosage levels as compared with controls.

nucleic acid¹⁰⁹ Another possibility is that streptomycin acts by coupling with thiol groups that are biologically essential to the bacterial cells⁹⁴

EFFECT IN VITRO AND IN EXPERIMENTAL INFECTIONS

In Vitro

Streptomycin has been shown to be bacteriostatic and bactericidal in vitro for a large number of gram-negative and gram-positive bacteria and for *Mycobacterium tuberculosis*. The range of sensitivity of a variety of organisms is presented in Table 2. Streptomycin is ineffective or has a limited effect against some spores,¹⁰⁰⁻¹⁰³ and the gram-positive spore-forming pathogenic anaerobes are resistant,¹⁰² as are most of the fungi,^{7, 102-103, 113-122} viruses¹³⁶⁻¹³⁸ and protozoa¹³⁹⁻¹⁴² that have been studied. Another antibiotic isolated from streptomycin-producing strains of *Streptomyces griseus* exerts an antifungal effect on *Cryptococcus neoformans* and on some nonpathogenic strains.⁷⁻⁸

In a consideration of the probable effectiveness of a chemotherapeutic agent against a particular micro-organism, it is customary to include the sensitivity or susceptibility of the organism to the agent in vitro and the effect of the agent on the course of experimental infections in suitable animals.

Sensitivity in vitro is usually expressed as the minimum effective or inhibiting concentration (M E C or M I C), and this is determined by a suitably devised experiment in which large numbers of organisms are pitted against various concentrations of streptomycin in a medium suited to the growth requirements of the organism. Such factors as reaction, size of inoculum, time of incubation and use of solid or liquid mediums vary according to circumstances and from worker to worker. Thus, it is difficult to compare the reported sensitivities obtained from different laboratories. Furthermore, since it has been shown that different strains of the same bacterial species may vary greatly in their susceptibility to streptomycin and since sensitivities are usually determined on material obtained by a single colony selection,* the figures can be accepted as showing merely the range or order of sensitivity. Some organisms such as *Pasteurella tularensis* and *Mycobacterium tuberculosis* are extremely sensitive, whereas others, such as *Pseudomonas aeruginosa*, may be just within the limits of the streptomycin levels attainable in the body.

Therapeutic correlations Some aspects of the correlation of in vitro sensitivity with the therapeutic value of streptomycin based on observations with *Haemophilus influenzae* are discussed by Alexander.⁵⁷ She suggests that sensitivity figures show the best agreement with therapeutic results if they are obtained by the use of large inoculums, mediums

designed for optimal growth and an adequate growth period. An unpredictable factor involved in the lack of such a correlation is the emergence of resistant strains during treatment. There are others, as evidenced by the fact that treatment of infections in man due to various strains of *Brucella* and *Salmonella* and to *E. typhosa* have been disappointing despite apparently favorable in vitro sensitivity values, adequate blood levels and failure to demonstrate the development of resistance.^{45, 62, 145}

Experimental Infections

Bacterial infections The protective action of streptomycin, in adequate dosage, for experimentally infected animals has been demonstrated with staphylococci,¹⁰² pneumococci,¹⁰² species of *Salmonella*,^{102, 146} *H. influenzae*¹²⁰ and meningococci.¹²⁷ The drug has been used for clearing mouse colonies of *Salmonella* infections.¹⁴⁷

The results in certain experimental infections are of interest. In experimental typhoid infections in mice the mortality rate was higher among infected animals receiving small doses of streptomycin than in similarly infected controls. Larger doses, however, were protective.¹⁰⁴ Infections with *Brucella abortus* in chick embryos were controlled,¹⁴⁸ and those in most guinea pigs were eliminated if adequate streptomycin therapy was instituted within a week.¹¹² Infections with *S. schottmülleri* and *P. aeruginosa* in mice, with *S. gallinarum* in chick embryos and *Proteus vulgaris* in animals were also prevented.¹⁴⁸ Chick embryos were also protected against *Pr. vulgaris* infections.¹⁴⁸ The course of infection in mice with *Pasteurella pestis* was favorably influenced, and the streptomycin effect was similar to that produced by sulfadiazine.^{128, 149} Streptomycin protected mice completely against fatal doses of *P. tularensis*.^{129†} Some protective therapeutic effect was noted against *H. pertussis* in mice.^{151, 150}

Streptomycin prolonged the life of mice experimentally infected with *Clostridium perfringens*.¹⁵¹ Streptomycin resulted in the survival of 92 per cent of mice infected with anthrax as against 58 per cent with penicillin and 5 per cent with sulfadiazine.¹⁵² There was only a slight effect on *Erysipelothrix rhusiopathiae* (erysipeloid) infections in mice—much less than that with penicillin.¹⁵³ Streptomycin seemed to be chemotherapeutically active against infections in rats with pleuropneumonia-like organisms and was more effective than gold compounds in the treatment of the associated arthritis.¹⁵⁴

Extensive studies on experimental infections caused by *Mycobacterium tuberculosis* have been carried out in guinea pigs,^{155, 156-157} mice^{158, 159} and chick embryos.¹⁶⁰ Streptomycin was shown to exert a marked suppressive effect on experimental tuberculosis in these animals. Combined therapy using streptomycin with Promin^{161, 162} or with Diasone¹⁶³ gave better results than any of these agents used singly.

*Infected urines or exudates may be planted directly on suitable agar plates containing graded concentrations of streptomycin, and the sensitivity of the infecting bacteria can thus be determined more promptly.¹⁴³ *In vivo* sensitivity test employing the chick embryo has also been

†The effect varies with the dose and time of institution of therapy. Latent infection without development of resistance is demonstrable in some surviving mice.¹⁵⁰

Morphologic and Cultural Properties of Resistant Bacteria

No changes were noted in the morphology of cells or colonies of gonococci or meningococci that had become resistant in vitro.¹²⁷ Loss of pigmentation and a reduction in the rate of carbohydrate fermentation were noted in two resistant strains of *Staph aureus*.¹⁹⁰ Changes in colony forms have been noted in strains cultivated from urinary-tract infections that had become resistant during treatment. Some species of *Proteus* lost their spreading property.¹⁹¹ A number of strains of *Shigella* showed atypical reactions in Russell's double-sugar medium after becoming resistant, but this aberration disappeared during the course of five to seven transfers through streptomycin-free mediums.⁵⁹

Two strains of *K. pneumoniae* that had become resistant on repeated passage through streptomycin-containing liquid mediums failed to ferment saccharose or to grow on citrate mediums. The ability to ferment saccharose returned in one of these strains after repeated transfer through streptomycin-free broth. Corresponding strains that had developed resistance during treatment and those in which resistance was rapidly enhanced by serial transfers on solid mediums containing streptomycin did not show these changes.¹⁹¹ Resistant strains of *Esch coli* do not synthesize biotin so well as sensitive strains.¹⁷⁶

One strain of *Brucella* that had become resistant during treatment showed two distinct forms: one grew fairly rapidly as a large colony but lost its characteristic biochemical reactions, the other grew slowly, formed smaller colonies, was more highly resistant and largely retained its morphologic and biochemical reactions. The former also showed some changes in morphology and staining properties as compared with the original sensitive strain. Growth of the resistant strain but not the sensitive ones was stimulated by sublethal concentrations of streptomycin.⁶²

All these changes were much less striking than those observed in organisms becoming resistant to penicillin.⁶² 195-197

Persistence of Acquired Resistance

Present evidence suggests that resistance once acquired, is usually a fairly stable property. Gonococci and meningococci that had acquired resistance by exposure to streptomycin in vitro retained their resistance over a period of three and a half months.¹²⁷ Five strains of *Shigella* remained resistant to over 1000 units per cubic centimeter when stored for six months at 4°C,⁵⁹ and the same strains retained appreciable resistance after fifty transfers, although there was a distinct falling off in the resistance of some. Similar results were obtained with a series of strains having somewhat lower levels of resistance.⁵⁹ Strains of staphylococci showed some decrease in resistance after transfer through broth,¹⁹⁰ whereas strains of *Staph aureus*

resistant to 2500 units per cubic centimeter retained their ability to grow well in 1000 units per cubic centimeter after four months in the refrigerator after several mouse passages and after being adapted to penicillin.⁶¹ Strains of *Mycobacterium tuberculosis* made resistant in vitro retained that resistance after repeated subculture in streptomycin-free mediums for four months.¹⁰⁷ Those obtained from patients under treatment remained resistant after residence in guinea pigs for ten weeks or more.¹⁹³ The resistance of a strain of *H. influenzae* was reduced considerably on subculture in streptomycin-free Leventhal broth.¹²⁰ The strain of *Br. abortus* referred to above retained its resistance during transfer in streptomycin-free mediums for three months.⁶² Strains from urinary infections that became resistant during treatment have retained the same degree of resistance after a hundred transfers in a streptomycin-free medium.¹¹⁷

Reciprocal Sensitivity (Cross Resistance)

Organisms becoming resistant to one antibiotic may remain sensitive to another.⁹⁹ When *Staph aureus* was made resistant to penicillin, streptomycin or streptothricin, a slight increase in resistance to streptomycin was noted in the organisms becoming resistant to streptothricin,¹⁵⁹ but no other reciprocal or cross resistance has usually been noted.⁶¹ 159 In one study, however, it was noted that two of five strains of staphylococci developing resistance to penicillin increased in resistance to streptomycin, whereas five strains becoming fast to streptomycin remained sensitive to penicillin.¹⁹⁰ Streptomycin-resistant meningococci are susceptible to penicillin in vivo and in vitro, and meningococci made resistant to penicillin remain susceptible to streptomycin.¹²⁷ Gonococci that acquired resistance to either agent remained susceptible to the other in vitro, although one strain of gonococcus became more susceptible to streptomycin after it had acquired resistance to penicillin.¹²⁷ Organisms acquiring streptomycin resistance remain sensitive to sulfonamides.¹⁰⁷ 189

Resistance and Virulence

There was no loss of virulence with increase of resistance in vitro of meningococci.¹²⁷ Strains of tubercle bacilli becoming resistant in vitro and in vivo remained virulent for mice¹⁹³ and guinea pigs.¹⁰⁷ 195

Mechanism of Development of Resistance

The mechanism by which resistance to an antibacterial agent develops in a culture is still a matter for speculation. The possibilities that have been mentioned include natural selection from a heterogeneous population, modification of the individual cell by establishment of alternative internal mechanisms within the cell or by qualitative or quantitative modifications of existing mechanisms, particularly enzyme systems, and changes in some center

tion contained 500 to 1000 units per cubic centimeter.³⁷ Intradermal injection caused slight local reddening, whereas subcutaneous injection of some lots resulted in edema, hemorrhage and necrosis.³⁷ No serious local effects were noted after intramuscular injection in rabbits.^{37, 184} Thromboses did not result from intravenous injections.³⁷ Rabbits receiving 100 mg per kilogram of body weight intrapleurally showed areas of hemorrhage and fibrous adhesions.³⁷

The application of 1250 units of streptomycin to the cerebral cortex of cats and monkeys has caused convulsive manifestations in 30 per cent of the animals tested. These effects were less marked than those produced by comparable amounts of penicillin, as judged by clinical and electroencephalographic observations. The cisternal injection of 2500 units or more in monkeys produced signs of severe cerebellar dysfunction manifested by unsteadiness, ataxia and inability to stand up, accompanied by spontaneous nystagmus and tremor of the head.¹⁸⁵ Rabbits tolerated 10 mg of streptomycin per kilogram of body weight intracisternally in 0.5 cc of distilled water, but respiratory failure and death resulted from a similar injection of 20 mg.¹⁸⁶

Special Effects

Streptomycin exhibited a low toxicity for rabbit spleen in tissue culture,¹⁸⁷ whereas concentrations of 200 units per cubic centimeter were mildly inhibitory for fibroblasts and epithelial cells.¹⁸⁴ Toxicity for developing chick embryos is likewise low, as noted above.

Some of the toxic effects encountered in the experimental use of streptomycin, such as lipid infiltration of the kidneys and liver in monkeys and the vestibular difficulties in dogs and man, seem to be caused by streptomycin itself. At least two other toxic effects are due to impurities. One of these impurities is a histamine-like substance that produces a vasodepressor action and has probably been responsible for many of the undesirable immediate effects. This action may be removed by incubation with histaminase.^{37, 188} The same substance may also be responsible for the antidiuretic action noted with some batches.³⁷ A separate impurity, not yet identified, gives rise to the increased intravenous toxicity of some batches.³⁷

RESISTANCE TO STREPTOMYCIN

It was pointed out above that different strains of the same organism may vary considerably in their sensitivity to streptomycin. Strains of considerable resistance may occur among species of bacteria that are predominantly sensitive. Even within a given strain, there may be great differences in the sensitivity of individual cells.

Development of Resistance in Vitro

It was early shown that organisms could develop increased resistance to streptomycin. Waksman³⁹ was able to increase the resistance of a strain of *Pr. vulgaris* by growing it in sublethal concentrations of streptomycin. Resistance is usually increased in vitro by exposing bacteria to increasing amounts in fluid or solid mediums, the medium chosen being one that would normally support good growth of the particular organisms. Experiments have also been carried out with urine as a culture medium.¹¹¹ The resistance of a variety of bacteria has been increased in relatively short periods with the use of one or another of these methods. The development of resistance has not been found to be associated with the production by the organism of a streptomycin-inhibiting substance analogous to penicillinase.^{36, 61, 62}

The following bacteria have been found to develop resistance in vitro: staphylococci,^{61, 189, 190} *Str. faecalis*,¹¹¹ meningococci,¹²⁷ gonococci,¹²⁷ *Esch. coli*,^{111, 191} *A. aerogenes*,^{111, 191} *K. pneumoniae*,^{100, 191} species of *Shigella*,⁵⁹ paracolon bacilli,¹⁹¹ *Pr. vulgaris*,^{111, 191} *Ps. aeruginosa*,^{111, 191} *H. influenzae*,¹²⁰ and *Mycobacterium tuberculosis* (human^{107, 192} and avian¹⁰⁷ forms and a non-pathogenic strain of *Mycobacterium*¹⁰⁷). The rate of increase in resistance is generally expressed by the number of transfers needed to habituate the organism to growing uninhibited in some arbitrarily chosen concentration. Resistance may be acquired rapidly, particularly by *Ps. aeruginosa*, meningococci and gonococci. Other organisms require a greater number of transfers, but less than fifty usually suffice in the majority of those studied.^{127, 191} The development of in vitro resistance of tubercle bacilli to both streptomycin and sulfonamides was retarded when the organisms were exposed to both agents simultaneously.¹⁰⁷

Most workers have not studied increases in resistance to levels greater than 1000 units per cubic centimeter because of the amount of streptomycin required. When this has been done, however, resistance to over 50,000¹⁹¹ and even over 75,000¹²⁷ units per cubic centimeter was readily obtained. These values represent essentially the limit of workable concentrations. The rate of increase in resistance seemed to be more rapid on surface than in liquid mediums.¹⁹¹

Effect of Streptomycin on Infections Produced by Resistant Strains

Mice infected with lethal doses of strains of *Staph. aureus*,⁶¹ *Mycobacterium tuberculosis*,^{120, 193} *H. influenzae*,¹⁴ and meningococci¹²⁷ that had been made resistant were not protected by large doses of streptomycin. Mice infected with the parent streptomycin-sensitive strains of similar virulence were protected, usually by small doses. Infections produced by the streptomycin-resistant strains of *Staph. aureus* were favorably influenced by penicillin.⁶¹

of organization of the cell¹⁹⁹ Demerec²⁰⁰ has visualized two possible methods by which organisms may develop resistance to penicillin by the acquisition of this characteristic through contact with the agent and as an inherited character originating through mutation. His experiments and those of Luria²⁰¹ suggest that the latter is the more probable method.

Highly resistant variants have been found in each of six strains of *Shigella* not previously exposed to streptomycin by subjecting large numbers of bacteria (up to eight billion) to the action of various concentrations of the antibiotic.⁵⁹ The ratio of resistant variants to total organisms was estimated at from 1 500,000,000 to 1 16,000,000,000, depending on the strain. Furthermore, susceptible organisms produced resistant variants in the same proportion, even after a series of six consecutive single-colony selections of presumably susceptible cells. A few variants of *A. aerogenes* and *K. pneumoniae* that were resistant to over 50,000 units per cubic centimeter were found to develop from inoculums of several billion relatively sensitive organisms on agar plates containing streptomycin.¹⁹¹ The development of resistance to streptomycin, therefore, seems to be the result of the occurrence of resistant variants and subsequent selection by a high streptomycin concentration.

Washed cells of two strains of *Shigella* suspended in physiologic saline solution and exposed to streptomycin for seven days under varying conditions failed to show any increase in resistance to streptomycin.⁵⁹ The failure of *Esch. coli* in the resting state to develop resistance on exposure to streptomycin has also been demonstrated.¹⁰¹

CASE 33191

PRESENTATION OF CASE

A seventy-eight-year-old widowed contractor was admitted to the hospital because of urinary frequency.

The patient had noted frequency, especially during cold weather, for over eight years. This had increased, until lately he had been voiding about every two hours during the day and once at night. He had had no dysuria, pyuria or hematuria. Following a recent cystoscopy the symptoms had become severer. On the morning of admission he was in a state of acute retention.

Physical examination showed slight enlargement of the heart. There was a soft, short systolic murmur at the apex and a loud rushing diastolic murmur that almost obscured the second sound. At the base there was a blowing systolic murmur, and the aortic second sound was not heard. The prostate was enlarged to twice the normal size. There was a moderate pitting edema of the ankles.

The blood pressure was 160 systolic, 85 diastolic. Examination of the blood disclosed a hemoglobin of 14.8 gm. The urine was red and gave a +++ test for albumin, and the sediment contained innumerable red cells. The nonprotein nitrogen was 30 mg per 100 cc. An x-ray film of the chest revealed a markedly enlarged heart, particularly in the region of the left ventricle. The aorta was tortuous and slightly dilated. An electrocardiogram revealed normal rhythm at a rate of 76 with considerable left-axis deviation, a low, diphasic T wave in Lead I and inverted T waves in Leads CF₁ and CF₂. A blood Hinton test was negative.

On the fourth hospital day a transurethral resection was performed. A moderate amount of bleeding was encountered. Near the end of the operation, the surgeon noticed a lack of return of irrigating fluid, and at the end of the operation it was noted that the abdomen was markedly distended. A suprapubic incision was made, and drainage of the peritoneal cavity and perivesical space was accomplished. Most of the fluid was anterior to the parietal peritoneum. At the end of the operation, the patient was in poor condition. Five per cent dextrose and water was given during the

operation, and immediately postoperatively two transfusions were administered. For the following week there was almost no urinary output. The nonprotein nitrogen by the third postoperative day had risen to 128 mg per 100 cc, the serum protein was 5 gm per 100 cc, and the chloride was 87 milliequiv and the carbon dioxide 20.3 milliequiv per liter. The suprapubic peritoneal drain was removed on the fifth postoperative day. The wound was in good condition, and peristalsis was noted. The nonprotein nitrogen, however, had risen to 185 mg per 100 cc, the chloride had fallen to 77 milliequiv and the carbon dioxide to 18.8 milliequiv per liter. On the following day the nonprotein nitrogen was 195 mg per 100 cc, the chloride was 79 milliequiv and the carbon dioxide 17.7 milliequiv per liter. On the sixth postoperative day a right nephrostomy and renal decapsulation were performed, and cloudy fluid was drained from the retroperitoneal region. Culture of this fluid revealed abundant colon bacilli and a few non-hemolytic streptococci. Twenty-four hours after decapsulation the nephrostomy tube began draining water-clear urine in increasing but small amounts and almost no urine was passed by way of the indwelling catheter in the bladder.

On the following day the patient suddenly became extremely short of breath and cyanotic. The neck veins were distended, the pulse was rapid, and rhonchi were heard in the chest. He was given aminophyllin, with dramatic improvement in breathing and color and some clearing of the chest signs. There were slight dullness and markedly diminished breath sounds at the right base, with some rales at both bases. On the next day the nonprotein nitrogen had reached 210 mg per 100 cc and the chloride 64 milliequiv and the carbon dioxide 22.2 milliequiv per liter. Two days later, the hemoglobin was 10 gm, the blood calcium was 7.2 mg, the phosphorus 14.7 mg, the nonprotein nitrogen 240 mg and the protein 6.2 gm per 100 cc and the chloride was 85 milliequiv, the carbon dioxide 19.4 milliequiv and the sodium 13.3 milliequiv per liter. On the next day a transfusion was administered. Twelve days after prostatectomy 450 cc of light, clear urine was collected from the nephrostomy tube, and the dressing was wet, but the nonprotein nitrogen had risen to 260 mg per 100 cc. On the following day the patient became extremely restless and expired.

DIFFERENTIAL DIAGNOSIS

DR. CHARLES BURNETT: The primary problem is to explain the renal failure in this patient, who, following transurethral resection, became anuric, developed uremia and died thirteen days after operation. I think that it is clear that he had prostatic obstruction of long standing, with urinary retention, and that he had benign hypertension and heart disease.

I suppose that one must also consider a benign nephrosclerosis, which was probably present to some extent, and it seems conceivable that acute renal insufficiency developed following the insult of operation, with nothing more demonstrable at autopsy. The patient may have had pyelonephritis and old hydronephrosis secondary to long-standing prostatic obstruction. The third possibility is the condition of so-called "reflex anuria," which occurs following urologic procedures. The anuria is presumably neurogenic in origin, and at autopsy no lesion can be demonstrated. I had not considered either bilateral cortical necrosis or periarteritis nodosa in this case, but they are, I suppose, possibilities.

I believe that the patient had hemoglobinuric nephrosis, in addition to uremia, hypertensive heart disease, calcareous aortic stenosis, some congestive heart failure, possibly some peritonitis and probably retroperitoneal infection.

DR. TRACY B. MALLORY: Dr. Smith, will you tell us your impression of the case?

DR. SMITH: The over-all impression is a sad one. This case began to go wrong when the spinal anesthetic did not work. After resection was started, the patient had pain, which I did not think at that time was due to extravasation of the urine, since I had hardly begun to resect. He was given inhalation anesthesia, and I went ahead with the resection. If he had not been under general anesthesia we would undoubtedly have noticed the leakage of fluid sooner, because these patients under spinal anesthesia are aware of pain when the fluid extravasates around the bladder. I thought that the point of leakage of the fluid was from the roof of the urethra, and when the operation was concluded and the patient lay flat on the table, it was seen that he had a marked swelling of the suprapubic region, so that we prepared for an abdominal operation as soon as possible.

As soon as the perivesical space was entered there was the escape of much slightly blood-stained fluid, which seemed to come largely from the perivesical space and more from the right side than the left. The peritoneum was opened purposely because the symptoms at the conclusion of the resection, when the patient quickly came out of general anesthesia, suggested that he had some intraperitoneal fluid. A small amount of clear fluid was obtained from the peritoneum, whereas the fluid from the perivesical space was bloody. Therefore, it did not seem likely that the rupture had extended into or involved the peritoneal portion of the bladder. A small drain was placed in the peritoneum, however. The bladder was opened, and a hasty exploration of the dome of the bladder revealed no rupture. The bladder was drained by a suprapubic tube.

It is surprising that although the heart seems to have been seriously damaged it took a terrific beating and got him through twelve days of the

hardest kind of going without failure. The case was handled carefully from the chemical point of view, Dr. Woodruff, the resident, followed the general rules of treatment in these cases that were laid down by Dr. George W. Thorn* in an admirable lecture that he gave before the Clinical Association of Genitourinary Surgeons. But it had become evident that the nonprotein nitrogen was going up steadily and rapidly, and the patient was still not excreting fluid. The experience that I had had with a few cases of anuria in the past indicated that decapsulation was certainly worth doing. The decapsulation and nephrostomy took about twenty minutes. The patient was much better the next morning, although he did not excrete fluid. He began to drain fluid two days after operation, but although 450 cc. of urine is a large enough output to enable a patient to get along without uremia if the urine is the product of a sufficient kidney, this was the product of an insufficient kidney with nephrosis of the lower nephrons. Nothing but water was being passed through the kidney. I suppose that if we could have kept him alive for another week or ten days the kidney tubular epithelium might have recovered enough so that he could have lived.

CLINICAL DIAGNOSES

Obstructing prostate
Hemoglobinuric nephrosis
Uremia

DR. BURNETT'S DIAGNOSES

Hemoglobinuric nephrosis
Uremia
Hypertensive heart disease
Calcareous aortic stenosis

ANATOMICAL DIAGNOSES

Hemoglobinuric nephrosis
Operative wounds: transurethral prostatectomy, drainage of perivesical space, and decapsulation of kidney
Prostatic hyperplasia
Endocarditis, chronic rheumatic, of aortic valve, with stenosis
Hypertrophy of heart
Arteriosclerosis generalized, moderate

PATHOLOGICAL DISCUSSION

DR. MALLORY: As Dr. Smith has said, a biopsy of one kidney was done at the time of decapsulation. Characteristic precipitated-hemoglobin casts were observed in the distal convoluted tubules. The biopsy, of course, had to be limited to the surface of the kidney and showed only the cortex. The major lesion in these cases is seen in the pyramids.

At autopsy we found evidence of a full-blown lesion—a great many pigment casts throughout the lower segments of the nephron, degeneration of the epithelium of Henle's loops and interstitial in-

May we see the x-ray films? Is there any evidence of left auricular enlargement?

DR STANLEY M WYMAN In the lateral view the retrocardiac space is not obliterated, and there is prominence in the region of the left ventricle. The concavity of the auricle is maintained at this point.

DR BURNETT How about the aorta?

DR WYMAN It is tortuous, but I do not believe that it is dilated. The transverse diameter seems to be within normal limits for a person of this age.

DR BURNETT Is there any evidence of congestive failure?

DR WYMAN I do not believe so.

DR BURNETT I believe that the cardiac lesion was caused by hypertensive heart disease and calcareous aortic stenosis and that the mitral murmur heard at the apex was due to hypertrophy and dilatation of the left ventricle. The electrocardiogram is also consistent with this diagnosis. There was some evidence of congestive failure in that pitting edema of the legs was observed. The laboratory data on admission showed proteinuria and hematuria and a compensated renal function, at least so far as the nonprotein nitrogen was concerned. Beyond that we are not given any data that tell what the renal reserve was.

I should like to ask a few questions. What was the nature of the fluid used in the irrigating solution? Was any evidence of hemoglobinuria, hemoglobinemia or icterus noted at any time postoperatively? Were sulfonamides administered at any time?

DR GEORGE G SMITH The fluid used was sterile tap water. The patient had not been given any sulfonamides except 1 gm of sulfadiazine after I cystoscoped him in my office. He had no icterus. It is unfortunate that we do not know about hemoglobinemia because Dr Woodruff has been checking that carefully on all transurethral prostatectomies, with interesting results. In this particular case he had the syringe ready, but in our haste to start the operation, he did not take the blood. Thus, in the one case in which we should particularly have liked to have a reading, no observation was made.

DR BURNETT From the description of the operation we may assume that a perforation of the bladder or the bladder neck had occurred. We are told that a considerable amount of bleeding was encountered and that the patient was in poor condition at the end of operation. Hence, he must have had at least some degree of shock, which I believe is the first factor that contributed to the fatal outcome.

Sterile tap water was used in the transurethral resection. It has recently been demonstrated by a number of workers that in this procedure a large number of veins are exposed in the prostatic bed, allowing ready access of the water to the veins and amounting to intravenous infusion of water, with the production of hemoglobinemia and renal failure.

Dr Joseph Ross¹ studied 23 cases recently, 15 of which developed hemoglobinemia, and in 6 the hemoglobinemia was of sufficient degree to produce hemoglobinuria. Two patients died, one of shock and the other of renal failure with a characteristic renal lesion. In this study the pressure of water used for irrigation was 100 mm. It is known that the pressure in the pelvic veins is 0-5 mm, and, indeed, in some cases it may be negative, so that it is not too surprising that intravascular hemolysis and hemoglobinemia result. This is a second factor that I believe to have contributed to the fatal outcome in the case under discussion.

The third factor is that two transfusions were given at the end of operation. We are not told whether a subsequent attempt was made to check the donors for the presence of incompatibility, but intravascular hemolysis of donor cells is always a possibility when a transfusion is given. Sulfonamides seem rather well excluded.

Hence, there were three factors capable of producing the hemoglobinuric or lower-nephron nephrosis that I believe was present in this case, and any one of these alone may produce it. Wounded battle casualties in severe shock and without any marked degree of pigment destruction have been shown to develop the lesion. The cause is thought to be partly renal ischemia, which is known to occur during shock and to persist for some time after recovery from shock. Hemolysis of one's own hemoglobin is known to produce the lesion if the hemolysis is of sufficient degree. Hemolysis of donor cells following transfusion of incompatible blood is too well known to require discussion.

The course in the case under discussion is compatible with such a diagnosis, as it is with any case of acute renal insufficiency. The progressive, severe azotemia, hypochloremia, acidosis, hypocalcemia, hyperphosphatemia and hyponatremia have all been seen and described in this syndrome. The episode on the eighth day may have represented pulmonary edema. In this particular type of acute renal insufficiency it has been demonstrated that the plasma volume is increased, — that is, that there is a true hydemia, — and I suspect that such an increase was present. The hypochloremia, as well as the fact that this man had a reduced cardiac reserve, readily explains the occurrence of acute pulmonary edema. Other possibilities are pulmonary infarction and atelectasis in the right lower lobe, as the signs suggested. The hemoglobin of 10 gm on the tenth day as compared to 15 gm on admission is confirmatory evidence of blood loss and possibly of a previous hemolysis.

The effect of decapsulation of the kidney is interesting. It appeared to increase the output of urine, especially on the side where it was done, and suggests that this procedure should be put to a fresh test in such cases.

malignant tumor of the esophagus, probably an epidermoid carcinoma

DR CHESTER M JONES Is the cardia of the stomach perfectly intact?

DR WYMAN I believe that the extreme distal esophagus and the cardia are normal

DR JONES In other words it appears that the tumor did not originate in the stomach, progressing up the esophagus. If it was carcinoma, I should be more inclined to call it an adenocarcinoma

DR TRACY B MALLORY On what basis? Because of its polypoid rather than constrictive growth?

DR JONES Yes

DR MCKITTRICK That is a pertinent suggestion and should have been considered in the diagnosis

CLINICAL DIAGNOSIS

Carcinoma of esophagus

DR MCKITTRICK'S DIAGNOSIS

Malignant tumor of esophagus, probably epidermoid carcinoma

ANATOMICAL DIAGNOSIS

Adenoacanthoma of cardia of stomach

PATHOLOGICAL DISCUSSION

DR SWEET This was a polypoid type of tumor, which is associated with the adenocarcinoma group, and it was one of the group of cases in which the cardia was actually 4 or 5 cm above the diaphragm. What looks like esophagus below the lesion was really stomach, so that this was a carcinoma of the cardia entirely above the diaphragm

DR MALLORY The specimen that Dr Sweet resected consisted of the lower part of the esophagus and the upper 7 cm of the stomach. A cancer was found centered at the cardiac orifice and extending in both directions, up into the esophagus and down into the cardia of the stomach. It was an adenocarcinoma, which in a few areas showed foci of squamous-cell formation and therefore falls in the group of tumors with both adenocarcinoma and squamous-cell carcinoma that are called adenoacanthomas. I do not believe that it is possible to be dogmatic about whether the origin was on the esophageal or the gastric side of the cardia, although adenoacanthomas are rare in the stomach and occasionally seen in the esophagus

inflammation I could distinguish no difference between the kidney that had been decapsulated and its mate. The proximal convoluted tubules and glomeruli, as usual, were normal except for a mild degree of dilatation. The lesion was, of course, indistinguishable from that which follows a transfusion reaction.

Checking back over cases of transurethral resection done in this hospital during the last seven or eight years, Dr. Firminger has found 5 similar cases. There have been none in patients on whom suprapubic or perineal prostatectomy has been performed.

The heart was moderately hypertrophied, weighing 490 gm., and the aortic valve had enough interadherence of the commissures to have produced slight stenosis. The coronary arteries showed only slight atheroma. The lungs were moderately edematous, as had been expected.

CASE 33192

PRESENTATION OF CASE

A sixty-four-year-old postmaster entered the hospital because of postprandial distress and regurgitation.

Two months before admission, following a drink of whisky, the patient had experienced the first episode of distress in the lower middle portion of the chest anteriorly, followed by regurgitation of some mucus. A short time later, the same thing happened after a swallow of ginger ale. During the next two weeks several similar episodes occurred, in the intervening periods he could swallow food and fluids without trouble. Six weeks before admission substernal distress and regurgitation of clear mucus began to follow swallowing of solids as well as fluids. On one occasion, while eating a tough piece of steak, he felt a sensation "as though a pineapple were being forced through an ulcer." He had reduced his diet, and in the two months he had lost 15 pounds.

Physical examination was essentially negative except for bilateral saphenous varicosities.

The temperature, pulse and respirations were normal, as was the blood pressure.

Routine examinations of the blood and urine were negative, and the total protein, nonprotein nitrogen, sugar and prothrombin time were normal, as was an electrocardiogram. A gastrointestinal series demonstrated a lobulated ulcerated tumor mass, measuring approximately 11 cm. in length, that involved the lower end of the esophagus and arose from its right posterior wall. It produced only slight obstruction to the flow of barium. The esophagus immediately above the diaphragm ap-

peared free of tumor. The stomach showed no evidence of pathologic change.

On the fourth and eleventh hospital days blood Hinton tests were reported positive.

An operation was performed on the twelfth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. JOHN B. MCKITTRICK: In this patient with symptoms of two months' duration there had apparently been no history of previous trouble. The symptoms were characteristic of esophageal disease. I have the impression from the record that the symptoms were intermittent and that the inability to pass food down the esophagus was not steadily progressive. One fleetingly thinks of esophageal spasm or cardiospasm with such a history, but as a rule, cardiospasm is of longer duration, rarely appearing primarily in a sixty-four-year-old man.

The physical examination does not help a great deal, nor do the other studies that were done in the hospital prior to operation. The patient had lost considerable weight — 15 pounds — in two months on a starvation diet. The record does not specify what the diet was, but I assume that he had confined himself to food that he could swallow easily and that this was quite limited. Apparently, at that point, he had been eating solid food rather than liquid. In contradistinction to carcinoma, it might be mentioned that patients with esophageal spasm often swallow solid food better than liquid. Is that correct, Dr. Sweet?

DR. RICHARD H. SWEET: I believe so, the symptoms are intermittent, at any rate.

DR. MCKITTRICK: As I read the record I was puzzled by the description of the x-ray examination and was not able to make a diagnosis. "A lobulated ulcerated tumor mass" — an unusual description — is mentioned. I suppose that a malignant tumor of the esophagus could be so described. I am interested to know whether this tumor showed evidence of infiltration in the wall of the esophagus or of pedunculation. Can infiltration of the wall of the esophagus be ruled out?

DR. STANLEY M. WYMAN: Not without fluoroscopy. On the film, this must be what is described as the lobulated mass — large confluent masses of tissue obliterating the normal mucosal pattern. The ulcer that is spoken of is probably this shadow.

DR. MCKITTRICK: It is a sessile, ulcerated, lobulated tumor. I think that the only diagnosis that I can make is a malignant tumor of the esophagus. Tumors of this size can develop in the course of the short history that this patient gave. Carcinoma of the esophagus with few symptoms referable to the esophagus does occur. It is conceivable that tumors more obvious than this are less symptomatic. The two positive blood Hinton tests are interesting, but I do not believe that the x-ray picture is characteristic of syphilis of the esophagus. My diagnosis is

The annual golf tournament of the Society will be held at the Woodland Golf Club, Newton, on the afternoon of May 20.

Once again the Committee on Arrangements — Sidney C. Wiggin, chairman, G. Guy Bailey, Harold G. Giddings, Robert L. Goodale and John F. Conlin — deserves praise for devising a program that should have great appeal to the members of the Society. All who can make the necessary arrangements should plan to attend!

THE FULMINANT FORM OF EPIDEMIC HEPATITIS

Lucke and Mallory¹ have recently described the clinical and anatomic findings in a group of fatal cases of acute epidemic hepatitis that may represent an entirely new form of this disease which they termed 'fulminant'. Epidemic hepatitis attained pandemic proportions during the war, it occurred in many parts of the world and probably in the armies of most, if not all, of the belligerent nations. In 1944 Lucke² described the pathology of this disease in 125 cases that were observed in the Army of the United States in 1942. During the period between August, 1943 and April, 1945 another series, consisting of 196 fatal cases, was accumulated at the Army Institute of Pathology. More than half the latter cases were of the acute form and were of intense severity, terminating fatally in less than ten days. By contrast, not a single equally fulminant case was encountered in the previous series, and this type of case has rarely been noted in other epidemics that have been reported. The usual duration of the fatal disease in Lucke's first series was from four to six weeks; in other words, the course of the fatal hepatitis was predominantly subacute.

This divergence in the duration of the fatal illness reflects the striking difference in the pertinent pathologic changes. Thus, in the fulminant form, the parenchyma of the liver is destroyed completely and uniformly, and this destructive process is accompanied by an intense inflammatory reaction. In the subacute form and in a quarter of the second series of cases, the destruction of the liver was incomplete; the involvement was characteristically

not uniform, regenerative hyperplasia of the surviving parenchyma led to the production of much new liver tissue and the inflammation was less pronounced.

The epidemiology of the cases also differed significantly. Most of the cases of hepatitis that occurred in 1942 followed the administration of yellow fever vaccine containing human serum. In the more recent series such vaccination had not been used but nearly half the patients had sustained combat injuries. Since most of the seriously wounded patients customarily received transfusions of whole blood, serum or plasma, it can be assumed that a high proportion of the wounded in the latter series were treated in this manner. It was not known, however, in how many cases the causal agent of hepatitis was introduced by therapeutic procedures, especially since large epidemics of hepatitis were prevalent in several of the theaters of war. The assumption that the cases among the wounded were examples of so-called "homologous serum hepatitis" seems justified largely by the relatively long interval between the time of the wound, and presumably of the first transfusion, and the time of onset of the clinical manifestation of the disease. About half the cases, which occurred in nonwounded persons, represented both the epidemic and the endemic variants of naturally occurring hepatitis. Lucke and Mallory's study is largely based on 94 fulminant cases in which the clinical duration did not exceed nine days but they also studied 39 additional cases that had a duration of from ten to nineteen days.

On the basis of epidemiology, 29 of the cases were classed as endemic and 72 as epidemic variants of spontaneous hepatitis and 77 cases were presumed to be homologous serum hepatitis following trauma and transfusions of blood or blood derivatives. A careful analysis showed that the epidemiologic type did not in any way determine either the clinical form or the pathological picture of the hepatitis, or whether the case was fulminant or subacute. There was no information whether the mortality rates were the same or different in the epidemiologic variants. The average mortality during the period covered by the study was 0.3 per cent. Serum hepatitis, however, tended to run a considerably shorter course than the naturally occurring disease.

COMING ANNUAL MEETING

THE one hundred and sixty-sixth anniversary of the Massachusetts Medical Society will be held at the Hotel Statler, Boston, on May 20, 21 and 22, and the program of the meeting appears elsewhere in this issue of the *Journal*

Owing to the fact that the program covers three full days, the meeting of the supervising censors and the annual meeting of the Council will be held in the late afternoon and early evening, respectively, on May 19

The first general session will begin at 9:05 a m on May 20, and four papers will comprise a symposium on industrial medicine. The annual meeting of the Society will be called to order at 11:00 a m and will be followed by the annual oration, "Medical Care in Our Free Society," by Dr Leland S McKittrick,

and by the annual luncheon. The second general session will begin at 2:00 p m and will be devoted to a symposium on the distribution of medical care for the people of Massachusetts. The speakers are Drs Elmer S Bagnall, Charles F Havden and Winthrop Adams and Messrs Reginald F Cahalane and Jarvis Hunt. The topics to be discussed include the attitude of the Massachusetts Medical Society, Blue Cross and Blue Shield, veterans' care and the industrial point of view. That evening, at 8:00, Dr William Dock, of Brooklyn, New York, will deliver the Shattuck Lecture, his title being "Clinical Significance of Circulatory Peculiarities of Some of the Vital Organs."

The third general session will open at 9:00 a m on May 21. The program lists seven papers on timely topics of general interest, such as infectious diarrhea of the newborn and the uses and abuses of chemotherapy. Four section meetings and luncheons are scheduled for the noon hour, and the fourth general session, which begins at 2:00 p m will comprise a symposium on bronchiectasis, consisting of five papers presenting the views of the pathologist, roentgenologist, internist, anesthetist and surgeon. A cocktail party will be held from 5:00 to 7:00, followed by the annual dinner, at which the guest speaker will be Dr Harrison H Shoulders, president of the American Medical Association.

The fifth and sixth general sessions will begin at 9:00 a m and 2:00 p m, respectively, on May 22. Fourteen talks on a miscellaneous group of topics are scheduled, and at noon four section meetings and luncheons will be held.

Although it has been necessary to eliminate the continuous motion-picture program and to cut down on the scientific exhibit owing to lack of space, the technical exhibit will be approximately as large as in previous years. Improvements in diagnostic aids and new therapeutic agents continue to appear at an amazingly rapid rate, and the technical exhibit offers an excellent opportunity for those who attend the meeting to become up to date.

The program for the wives of members includes a reception and tea at the Women's City Club, Boston, on the afternoon of May 20 and luncheon at The Country Club, Brookline, on the following day.

The annual golf tournament of the Society will be held at the Woodland Golf Club Newton, on the afternoon of May 20

Once again the Committee on Arrangements — Sidney C Wiggan, chairman, G Guy Bailey Harold G Giddings Robert L Goodale and John F Conlin — deserves praise for devising a program that should have great appeal to the members of the Society All who can make the necessary arrangements should plan to attend!

THE FULMINANT FORM OF EPIDEMIC HEPATITIS

Lucké and Mallory¹ have recently described the clinical and anatomic findings in a group of fatal cases of acute epidemic hepatitis that may represent an entirely new form of this disease which they termed "fulminant" Epidemic hepatitis attained pandemic proportions during the war, it occurred in many parts of the world and probably in the armies of most, if not all, of the belligerent nations In 1944 Lucké² described the pathology of this disease in 125 cases that were observed in the Army of the United States in 1942 During the period between August, 1943 and April, 1945, another series, consisting of 196 fatal cases was accumulated at the Army Institute of Pathology More than half the latter cases were of the acute form and were of intense severity terminating fatally in less than ten days By contrast, not a single equally fulminant case was encountered in the previous series, and this type of case has rarely been noted in other epidemics that have been reported The usual duration of the fatal disease in Lucké's first series was from four to six weeks in other words, the course of the fatal hepatitis was predominantly subacute

This divergence in the duration of the fatal illness reflects the striking difference in the pertinent pathologic changes Thus, in the fulminant form, the parenchyma of the liver is destroyed completely and uniformly, and this destructive process is accompanied by an intense inflammatory reaction In the subacute form and in a quarter of the second series of cases, the destruction of the liver was incomplete, the involvement was characteristically

not uniform, regenerative hyperplasia of the surviving parenchyma led to the production of much new liver tissue and the inflammation was less pronounced

The epidemiology of the cases also differed significantly Most of the cases of hepatitis that occurred in 1942 followed the administration of yellow-fever vaccine containing human serum In the more recent series such vaccination had not been used, but nearly half the patients had sustained combat injuries Since most of the seriously wounded patients customarily received transfusions of whole blood, serum or plasma it can be assumed that a high proportion of the wounded in the latter series were treated in this manner It was not known however, in how many cases the causal agent of hepatitis was introduced by therapeutic procedures especially since large epidemics of hepatitis were prevalent in several of the theaters of war The assumption that the cases among the wounded were examples of so-called "homologous serum hepatitis" seems justified largely by the relatively long interval between the time of the wound, and presumably of the first transfusion, and the time of onset of the clinical manifestation of the disease About half the cases, which occurred in nonwounded persons, represented both the epidemic and the endemic variants of naturally occurring hepatitis Lucké and Mallory's study is largely based on 94 fulminant cases in which the clinical duration did not exceed nine days, but they also studied 39 additional cases that had a duration of from ten to nineteen days

On the basis of epidemiology, 29 of the cases were classed as endemic and 72 as epidemic variants of spontaneous hepatitis, and 77 cases were presumed to be homologous serum hepatitis following trauma and transfusions of blood or blood derivatives A careful analysis showed that the epidemiologic type did not in any way determine either the clinical form or the pathological picture of the hepatitis, or whether the case was fulminant or subacute There was no information whether the mortality rates were the same or different in the epidemiologic variants The average mortality during the period covered by the study was 0.3 per cent Serum hepatitis, however, tended to run a considerably shorter course than the naturally occurring disease

Clinically, the fulminant form of hepatitis was characterized by its abrupt onset and by its severity. It was usually ushered in by one of two syndromes—an "infectious type," in which the disease began with fever, chilliness, shaking chills, malaise, generalized aching and pains in the joints, back and eyes, with gastrointestinal symptoms usually following in a day or so but rarely dominating the picture, or a "gastrointestinal type," with anorexia, nausea and epigastric discomfort as the presenting symptoms. These two types were about equally frequent and often occurred side by side during various epidemics. In the fulminant cases, the initial symptoms sometimes merged with those of the terminal stage, but the subsequent clinical manifestations bore no relation to the prodromal symptoms.

The temperature ranged from 95 to 104° F., with an average of 102°, and usually declined with the onset of jaundice. There was generally a terminal sharp rise in temperature coincident with the onset of profound cerebral disturbances. In contrast to the deep jaundice commonly observed in the subacute form, the jaundice in fulminant hepatitis was often mild, and several anicteric cases were observed. Moderate degrees of nitrogen retention and lowered blood sugar levels were among the noteworthy laboratory findings.

The pathologic lesions, other than those in the liver, were relatively slight. As previously mentioned, the changes in the liver were characterized by an extreme and often complete destruction of the hepatic cells and a marked inflammatory reaction, the involvement usually being uniform throughout the liver. The gross appearance gave no indication either of the extent of parenchymatous destruction or of the degree of inflammatory infiltration. The organ was usually flaccid and moderately shrunken, and the capsule was smooth or finely wrinkled. The cut surface generally presented an exaggerated "nutmeg" pattern, although sometimes it resembled that of an acutely congested spleen. Microscopically, the destructive

process was limited to the liver cells. Practically all the parenchymal cells were necrotic and had undergone lysis, and the resultant debris had already been removed at the time of death. The inflammatory cells consisted of mononuclear forms—reticuloendothelial derivatives, plasma cells and lymphocytes. Regenerative hyperplasia of the parenchyma was minimal and was confined to the biliary rather than to the hepatic epithelium. In most cases the pathologic changes in the liver were obviously older than the clinical history suggested, but sometimes the reverse was true.

The kidneys in the majority of cases were the site of fat storage, especially within the cells of the proximal convoluted tubules. There were no significant degenerative changes, and the findings were considered to be the result of the sudden liberation of large amounts of fat from the destroyed liver cells. There was no correlation between the degree of fat storage and the nitrogen retention. The so-called "hepatorenal syndrome," as usually defined, was not observed. Although marked nervous disturbances were noted clinically in the terminal stages, the histologic changes in the brain were usually slight, consisting of a mild and non-specific encephalopathy. Ascites was present in approximately a fourth of the cases of fulminant hepatitis, and its production was thought to be the result of acute venous stasis in the liver. The incidence of ascites and its extent, however, seemed to be directly proportional to the duration of the disease and were not related to the weight of the liver.

The factors responsible for the appearance of this fulminant form of hepatitis were difficult to assess. It was suggested that a number of more or less interrelated host factors, such as fatigue, trauma and nutritional disturbances, played a dominant role, rather than any specific property of the strain or the amount of the infectious agent.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

NEW DIRECTOR

Nicholas J. Fiumara, M.D. health officer of the Berkshire District of the State Department of Public Health, has been promoted to director of the Division of Venereal Diseases, pending qualification by the Division of Civil Service.

Dr. Fiumara succeeds Dr. George E. Perkins, of Belmont who died suddenly from injuries sustained in an automobile accident.

A former lieutenant in the Navy Medical Reserve Corps, Dr. Fiumara served with the Navy from June 1945 to July 1946. He held the successive posts of medical officer aboard the *USS Monomoy*, venereal-disease control officer in the Caribbean Theater and commanding officer of Epidemiology Unit 22, which saw service on the West Coast.

Since his detachment from the Navy last year, Dr. Fiumara has been attending the Harvard School of Public Health, from which it is expected he will receive the degree of Master of Public Health in June.

He is a member of the Massachusetts Medical Society, American Public Health Association and Massachusetts Public Health Association and a fellow of the American Medical Association.

COMMENTS
Diphtheria once again was the leading disease of the month. The number of cases reported has essentially the same ratio to those of 1946 and the seven-year median as that reported in February, however, the number of cases shows an increase of 18 cases over the number of cases reported in February.

Chicken pox was still increased as compared with the number of cases reported in March 1946, but the excess was not so marked, being approximately three times the number of

cases reported in March, 1946, and three times the seven-year median.

Measles and German measles both showed a marked drop compared to the number of cases reported in March, 1946, and to the seven-year median. German measles, in particular being approximately one sixth the number of cases reported in March, 1946 and one third the seven-year median.

Diseases above the seven-year median were dog bite, bacillary dysentery, poliomyelitis, salmonellosis and undulant fever.

Scarlet fever is at the lowest level since 1918.

Below the seven-year median are gonorrhea, meningitis, lobar pneumonia, syphilis, typhoid fever and whooping cough.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Diphtheria was reported from Abington, 1, Belmont, 1, Boston, 30, Cambridge, 1, Chelsea, 3, Chicopee, 5, Easthampton, 2, Everett, 1, Lowell, 1, Lynn, 1, Medford, 1, New Bedford, 4, Newbury, 1, Newton, 1, Norton, 1, Peabody, 1, Reading, 2, Revere, 5, Saugus, 1, Somerville, 3, Southwick, 1, Wellesley, 1, West Newbury, 1, West Springfield, 1, Winchester, 1, Winthrop, 1, total, 72.

Dysentery amebic was reported from Boston, 1, Cambridge, 1, Quincy, 1, total, 3.

Dysentery bacillary was reported from Melrose, 3, Worcester (State Hospital), 6, total, 9.

Encephalitis infectious was reported from Middleboro, 1, New Bedford, 1, total, 2.

Hookworm was reported from Lowell, 1, total, 1.

Lymphocytic chorion meningitis was reported from Weymouth, 1, total, 1.

Malaria was reported from Acton, 1, Boston, 1, Lowell, 1, Lynn, 2, Medford, 2, Worcester, 1, total, 8.

Meningitis meningococcal was reported from Boston, 1, Middleboro, 1, Swampscott, 1, total, 3.

Meningitis Pfeiffer bacillus was reported from Boston, 1, Brockton, 1, Revere, 1, total, 3.

Meningitis pneumococcal was reported from Boston, 1, total, 1.

Meningitis other forms was reported from Mansfield, 1, total, 1.

Meningitis, undetermined, was reported from Cambridge, 3, Fall River, 1, Milton, 1, Newton, 1, Salem, 1, Wilmansett, 1, Worcester, 1, total, 9.

Poliomyelitis was reported from Chicopee, 1, Lynn, 1, total, 2.

Salmonellosis was reported from Belmont, 1, Boston, 2, Gardner, 1, Holyoke, 1, Melrose, 1, Peabody, 2, Quincy, 1, Salem, 1, Somerville, 1, Southbridge, 2, Springfield, 1, Sutton, 1, total, 15.

Septic sore throat was reported from Boston, 5, Bourne, 1, East Bridgewater, 1, Grafton, 1, Holyoke, 1, Malden, 1, Merrimack, 1, Newburyport, 1, West Newbury, 2, total, 14.

Tetanus was reported from Weymouth, 1, total, 1.

Trachoma was reported from Boston, 1, Cummingtown, 1, total, 2.

Trichinosis was reported from Boston, 5, Malden, 1, Middleboro, 1, Wenham, 2, total, 9.

Tularemia was reported from Grafton, 1, total, 1.

Typhoid fever was reported from New Bedford, 1, total, 1.

Undulant fever was reported from Adams, 1, Amesbury, 1, Auburn, 1, Dartmouth, 1, Holyoke, 1, Springfield, 1, Worcester, 1, total, 7.

OFFICERS OF THE MASSACHUSETTS MEDICAL SOCIETY, 1946-1947

*Blackstone*DR. EDWARD P. BAGG, *President-Elect*

PROGRAM OF THE ONE HUNDRED AND SIXTY-SIXTH ANNIVERSARY OF THE MASSACHUSETTS MEDICAL SOCIETY

Monday, Tuesday, Wednesday and Thursday, May 19, 20, 21 and 22, Hotel Statler, Boston

The Registration Desk will be located on the Mezzanine Floor, and all who attend the meeting are requested to register

MONDAY AFTERNOON, MAY 19

- 4:00 Supervising Censors' Meeting (PARLOR C)
6:00 Cotting Supper for Councilors (PARLORS A AND B)

discussion by DR HARRIET L HARDY, Boston Physician, Division of Occupational Hygiene, Commonwealth of Massachusetts

- 9:30 *The Control of Respiratory Infections in Industry*
DR. GEORGE F WILKINS, Boston Assistant medical director, New England Telephone and Telegraph Company With a discussion by Dr

DR. DWIGHT O'HARA, President

Backus

DR ISAAC S F DODD, Vice-President

MONDAY EVENING, MAY 19

- 7:00 Annual Meeting of the Council (GEORGIAN ROOM)

TUESDAY MORNING, MAY 20

First General Session

GEORGIAN ROOM

- DR. DANIEL L LYNCH, *Chairman*
DR. GERALD L DOHERTY, *Co-chairman*

Symposium on Industrial Medicine

- 9:05 *Toxic Effects of Gases and Vapors* DR. MARSHALL CLYTON, Boston Associate in industrial hygiene, Harvard School of Public Health With a

ARLIE BOCK, Boston Professor of hygiene, Harvard University

- 9:55 *Rehabilitation of the Employee Injured in Industry*
DR ALEXANDER P AITKEN, Boston Medical director, Rehabilitation Center, Liberty Mutual Insurance Company, Boston With a discussion by DR AUGUSTUS THORNDIKE, JR, Boston Chief surgeon, Department of Hygiene, Harvard University

- 10:20 *Occupational Dermatoses* DR JOHN G DOWNING, Boston Professor of dermatology, Tufts College Medical School and Boston University School of Medicine

11 00 Annual Meeting of the Massachusetts Medical Society (GEORGIAN ROOM)

Annual Oration (following annual meeting) **Medical Care in Our Free Society** DR LELAND S MCKITTRICK, Boston Surgeon-in-chief, Palmer Memorial Hospital, visiting surgeon, Massachusetts General Hospital

Annual Luncheon (PARLORS A, B AND C) tickets must be procured in advance of the meeting

TUESDAY AFTERNOON, MAY 20

Second General Session

GEORGIAN ROOM

DR REGINALD FITZ, *Chairman*

DR ALBERT A HORNER, *Co-chairman*

Symposium The Distribution of Medical Care for the People of Massachusetts

2 00 *Principles of the Massachusetts Medical Society* DR ELMER S BAGNALL, Groveland Past-president, Massachusetts Medical Society

2 25 *The Contribution of the Blue Cross* MR REGINALD F CAHALANE, Boston Executive director, Massachusetts Hospital Service, Inc., and Massachusetts Medical Service, Inc., vice-chairman, Blue Cross Commission

2 50 *The Contribution of the Blue Shield* DR CHARLES G HAYDEN, Boston Medical director, Massachusetts Hospital Service, Inc., and Massachusetts Medical Service, Inc., member of the Commission, Associated Medical Care Plans

3 15 *Medical and Hospital Care of the Veterans in Massachusetts* DR WINTHROP ADAMS, Boston Branch medical director, Veterans Administration, Boston

3 40 *What Industry Thinks About the Program* MR JARVIS HUNT, North Attleboro General counsel, Associated Industries of Massachusetts, former president, Massachusetts State Senate

4 05 *Question-and-Answer Period*

TUESDAY EVENING, MAY 20

GEORGIAN ROOM

8 00 **The Shattuck Lecture** Clinical Significance of Circulatory Peculiarities of Some of the Vital Organs DR WILLIAM DOCK, Brooklyn, New York Professor of medicine Long Island College of Medicine, director of medical service, College Division, King's County Hospital

WEDNESDAY MORNING, MAY 21

Third General Session

GEORGIAN ROOM

DR ISAAC S F DODD, *Chairman*

DR ALLEN RICE, *Co-chairman*

9 00 *The Advantages of the Extraperitoneal Cesarean Section* DR ROY J HEFFERNAN, Brookline Visiting obstetrician and gynecologist, Carney Hospital,

CORRESPONDENCE

DIGITALIS

To the Editor Another excellent article on medical progress, namely "Digitalis," by Drs. Freedberg and Zoll, appeared in the December 6, 1946, issue of the *Journal*. A paragraph gives emphasis as an example of the unsatisfactory state of our knowledge concerning one of our most extensively studied and generally used drugs. It states:

One cat unit is defined as the amount of digitalis per kilogram of cat weight that produces a lethal effect under certain defined conditions. One *USP XII* unit of digitalis represents the same potency as 0.1 gm. of the *USP* digitalis reference standard powder, when assayed as directed. The digitalis leaves from which the reference powder was made, however, were of high potency, so that 1 *USP XII* unit is equivalent to 20 per cent more than 1 cat unit. It is particularly important for the physician to know the digitalis preparation he is using since the clinical effect of digitalis, standardized according to *USP XII*, is approximately 25 per cent weaker than *USP XI*, which in turn is approximately 50 per cent stronger than *USP A*.

In reading the article one also learns that the cat method of assay measures the lethal potency of digitalis and not specific therapeutic action, also that by comparative assays in cats and human beings, a group of digitalis preparations with the same strength in cat units showed a tenfold range in potency in human subjects.

This, obviously, is hardly a satisfactory standardization of a therapeutic agent. Perhaps it is somewhat natural, therefore, for those of us who are not cardiologists to ask why we continue to perplex physicians with cat units and complicated discussions of digitalis therapy when a crystallized digitaline has been available since 1866 that is a thousand times as therapeutically effective as digitalis leaf and has certain other advantages. Quoting again from the same progress article:

In summary, the advantages of digitoxin are that it is a pure chemical that is stable and does not require bioassay and that it is completely absorbed from the gastrointestinal tract, so that oral and intravenous doses are the same and interchangeable. Furthermore the small amount of digitoxin necessary for digitalization permits administration of a large fraction in a single dose, with only a small incidence of local gastrointestinal irritation. The rapid onset of action makes for quick digitalization by the oral route

so that intravenous administration is rarely necessary. The prolonged duration of action, like that of whole-leaf digitalis, makes for easy maintenance. It is thus the drug of choice when a purified preparation is desired.

Is it naïveté or common sense that also leads the non-cardiologist to ask when a purified preparation is not desirable?

If the answer is one of expense this could be overcome by an increased demand by physicians for the pure product. If it is because of conservative reverence for a time-tested therapeutic agent the seventy years of digitoxin would appear to remove that product from the classification of *rosaliaux*.

UNLAWFUL IMPORTATION OF NARCOTIC DRUGS

To the Editor From time to time the Bureau of Narcotics and the Bureau of Customs have received complaints from physicians when narcotic drugs have been seized from their medical bags at the time of re-entering the United States from a visit to Mexico or Canada.

In view of the above fact the Commissioner of Narcotics has requested the following notice be printed in medical journals of states close to either Canada or Mexico:

Under the provisions of the Narcotic Drugs Import and Export Act it is unlawful for a physician to carry narcotic drugs in his medical bag back and forth between the United States and Mexico and between the United States and Canada. Narcotic drugs found in the possession of a physician on returning to the United States are seized and forfeited. Because of lack of knowledge of the law many physicians are caused embarrassment and inconvenience when traveling between this country and Mexico or Canada. This information is published in order that physicians may be correctly informed with reference to this provision of the federal law.

BOOK REVIEWS

Public Health and Welfare Reorganization: The postwar problem in the Canadian provinces. By Harry M. Cassidy, Ph.D. 8°, cloth, 464 pp. Toronto: Ryerson Press, 1945. Cloth \$4.50, paper \$3.50.

This work is a sequel to the author's *Social Security and Reconstruction in Canada*, published in 1943. The text is divided into four parts. The first discusses premises for provincial planning, with an analysis of the present system and suggested adjustments in the provincial systems. The second and third are devoted to British Columbia, the Prairie provinces, Ontario, Quebec and the Maritime provinces. The history of public health in these localities, the present status and suggested programs for the future are considered in detail. The fourth part is a summary pointing out the flaws in the present system and outlining the principles of reorganization. The importance of local units and national leadership is stressed.

On the basis of his practical experience and study the author is convinced that there are serious weaknesses in the Canadian provincial and local social services, including the health services. He believes that drastic changes in organization and administration are required before these services can reach high standards.

This document should be in all public-health collections.

Clinical Roentgenology of the Heart. By John B. Schwedel, M.D. *Annals of Roentgenology*, Volume XVIII. 4°, cloth, 380 pp., with 749 illustrations. New York: Paul B. Hoeber, Incorporated, 1946. \$12.00.

This volume presents a brief summary of the present status of the roentgenologic study of the heart and great vessels.

There are many illustrations, including not only roentgenograms but also diagrams and photographs of pathological specimens. The text is clear, the pictures are well selected, and the volume is well printed and bound. Of particular interest is the emphasis on normal variations in Chapter 4.

As in any brief work of the sort, some things are too much abbreviated. It would be of value to add illustrations of a dissecting aneurysm of the aorta, both before and after its development. A more typical illustration of constrictive pericarditis is also desirable and, similarly, a roentgenogram of the heart showing auricular septal defect without mitral stenosis. Tricuspid atresia might well have been added as one of the more newly recognizable congenital defects. It should be noted that, on occasion, funnel chest may compress as well as displace the heart and thus embarrass the circulation.

The electrocardiogram reproduced in Figure 53J on page 90 is upside down, as is that in Figure 72C on page 128. In the last sentence of page 319 "left" should read "right."

This book can be recommended as an up-to-date exposition of roentgenology of the heart and great vessels.

It's How You Take It By G. Colket Caner, M.D. 12°, cloth, 152 pp. New York: Coward-McCann, Incorporated, 1946. \$2.00.

Physicians will find this book a practical volume to recommend to patients as an adjunct to psychotherapy. A troubled person can read it without risk and can find in it pertinent discussion of problems closely related to his own, and a healthy person can gain through it understanding that will enable him to function at a higher level of effectiveness and contentment. The book is concise, simple and free from technical language.

The literary device of posing questions, used in the book, stimulates interest and attention. Dr. Caner's answers, which are constructive and replete with wholesome ideas, make clear what a person can do toward helping himself. They give an understanding of psychosomatic reactions and of the effect of various attitudes on relations with others and on emotional stability. The common sense and idealism of the book make it particularly suited to young persons but it will also appeal to adults particularly to parents and teachers. The volume could be profitably used in high schools as a basis for the teaching of mental hygiene, whose preventive aspects it covers thoroughly and soundly. It is a book to be studied and to be read thoughtfully over and over again. Used in this way, it will be extremely helpful.

Diseases of the Adrenals By Louis J. Soffer, M.D. 8°, cloth, 304 pp., with 42 illustrations and 2 colored plates. Philadelphia: Lea and Febiger, 1946. \$5.50.

This book is constructed along orthodox lines and covers the adrenal gland from medulla to cortex. One of its most valuable features is an account of methods now in use for determining the concentrations of sodium or potassium in serum and urine and for assaying the excretion of androgens, estrogens and 17-ketosteroids. The part of the monograph that describes Addison's disease and the clinical manifestations of the different tumors that may involve the adrenal glands is well written. The color plates are excellent. On the whole, the volume represents much industry and can be recommended as a useful work of reference.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Mongolism and Cretinism. A study of the clinical manifestations and the general pathology of pituitary and thyroid deficiency. By Clemens E. Benda, M.D., director, Wallace Research Laboratory for the Study of Mental Deficiency, Wrentham, Massachusetts, instructor in neuropathology, Harvard Medical School, and assistant in psychiatry, Mas-

sachusetts General Hospital. 8°, cloth, 310 pp., with 10 illustrations and 48 tables. New York: Grune and Stratton, 1946. \$6.50.

Dentistry. An agency of health service. By Malcolm W. Carr, D.D.S., director of oral surgery and visiting oral surgeon, Metropolitan Hospital, attending oral surgeon, St. Luke's Hospital, Knickerbocker Hospital, Polyclinic Hospital and Flower and Fifth Avenue Hospitals, consultant oral surgeon, Roosevelt Hospital, and lecturer in oral surgery, Graduate School of Medicine, University of Pennsylvania. Studies of the New York Academy of Medicine, Committee on Medicine and the Changing Order. 8°, cloth, 216 pp. New York: The Commonwealth Fund, 1946. \$1.50.

Jerome Carden By James Eckman. 4°, paper, 120 pp. Baltimore: Johns Hopkins Press, 1946. \$2.00.

Eight Years of Public Health Work. Jones County, Mississippi 1937-1944. By Harry E. Handley, M.D., assistant director, Division of Public Health, The Commonwealth Fund, and Carolina R. Randolph, director of studies, Division of Public Health, The Commonwealth Fund. 12°, paper, 80 pp., with 47 tables. New York: The Commonwealth Fund, 1946. 50 cents.

Modern Development of Chemotherapy. By E. Havinga, H. W. Julius, H. Veldstra, and K. C. Winkler. 8°, paper, 175 pp., with 31 illustrations and 8 tables. New York: Elsevier Publishing Company, Incorporated, 1946. \$3.50.

Autopsy, Diagnosis and Technique. By Otto Saphir, M.D., pathologist, Michael Reese Hospital, and professor of pathology, University of Illinois Medical School, Chicago. With a foreword by Ludwig Hektoen, M.D. Second edition, revised and enlarged. 12°, cloth, 405 pp., with 69 illustrations. New York: Paul B. Hoeber, Incorporated, 1946. \$5.00.

Medicine in Industry. By Bernhard J. Stern, Ph.D., lecturer in sociology, Columbia University, and visiting professor of sociology, Yale University. Studies of the New York Academy of Medicine. Committee on Medicine and the Changing Order. 8°, cloth, 209 pp. New York: The Commonwealth Fund, 1946. \$1.50.

The Diagnosis and Treatment of Pulmonary Tuberculosis. By Moses J. Stone, M.D., assistant professor in medicine, Boston University School of Medicine, instructor in medicine, Tufts College Medical School, and physician-in-chief, Chest Clinics, Beth Israel and Massachusetts Memorial Hospitals, and Paul Dufault, M.D., superintendent, Rutland State Sanatorium, Rutland, Massachusetts. With a foreword by Henry D. Chadwick, M.D. 12°, cloth, 325 pp., with 93 illustrations. Philadelphia: Lea and Febiger, 1946. \$3.50.

Mother and Baby Care in Pictures. By Louise Zabriskie, R.N., director, Maternity Consultation Service, New York City, lecturer, New York University, and field director, Maternity Center Association, New York City. Third edition, modernized. 8°, cloth, 203 pp., with 229 illustrations and 7 tables. Philadelphia: J. B. Lippincott Company. \$2.00.

Complete Handbook on State Medicine. By J. Weston Walch. 4°, paper, 170 pp. Portland, Maine: J. Weston Walch, 1946. \$2.50.

BACTERIAL ENDOCARDITIS TREATED WITH PENICILLIN*

Observations in Nine Cases

STEWART H. JONES, M.D.,[†] AND FAE TICHY, M.D.[‡]

BOSTON

THE unprecedented cures of subacute bacterial endocarditis with penicillin have stimulated fresh interest in this heretofore fatal disease. During the last two years 9 patients have been treated and followed at the Lahey Clinic. The abstracts of these cases are presented for several reasons: unusual organisms were encountered in 2, surgery was instrumental in curing 1, and 1 represented the bacteria-free stage of bacterial endocarditis. The need for individualization of treatment is demonstrated, and several suggestions are made for improving present-day results.

CASE 1 A 59-year-old clerk was admitted to the hospital on January 1, 1946. He complained of weakness and subternal discomfort of 2 years' duration and a loss of 16 pounds in weight during the previous 2 months. For 6 months occasional temperature elevations had occurred. There was no history of rheumatic fever or syphilis.

Physical examination showed a pale and sickly patient with moderate pitting edema of the ankles. Slight exertion caused dyspnea. A to-and-fro murmur, loudest at the aortic area, and accentuation of the pulmonic second sound were detected. The cardiac apex was in the anterior axillary line in the sixth intercostal space. The blood pressure was 170/40 to 0, and the pulse was of water-hammer type. Other findings were basal pulmonary rales, petechiae, clubbing of the fingers, splenomegaly and tremor of the head and hands. The patient was given digitalis and a salt-free diet and kept in bed. There was no fever until the 8th day, when the temperature rose to 101°F.

Streptococcus mutraceus was isolated from the blood. There was a mild hypochromic anemia with a normal number of leukocytes, 47 per cent of which were young forms. Blood Hinton, Kahn and Wassermann tests were negative. Urinalyses showed no abnormal findings. The blood non-protein nitrogen was 35.8 mg. per 100 cc. Roentgenograms showed enlargement of the heart in all dimensions, congestion of the lungs and no dental infection. Electrocardiograms revealed a sinus rhythm, left-axis deviation, and occasional extrasystoles.

Figure 1 illustrates the penicillin and sulfadiazine blood levels and the results of blood cultures and penicillin sensitivity tests correlated with the temperature chart. The response to penicillin was dramatic. The temperature rapidly returned to normal, and the blood cultures became sterile. Concurrent heart failure progressed, however, in spite of digitalization, avoidance of sodium, an acid-ash diet and

mercurial diuretics. The patient left the hospital on the 40th day to convalesce nearer home, and 10 days later died from heart failure. Autopsy was not performed.

The value of determining both the penicillin sensitivity of the organism and the penicillin blood levels was confirmed in this case. Had the usual arbitrary doses been used without knowledge of these two determinations, insufficient penicillin would have been administered. Intramuscular administration resulted in a rapid decrease of penicillin in the blood—from 5 units per cubic centimeter an hour after injection to 0.65 units three hours later. Constant intravenous administration gives constant blood levels¹ and appears to be more efficient.

Streptococcus mutraceus, a variety of *Str. bovis*, is rarely reported in subacute bacterial endocarditis. Its true incidence in this disease cannot be determined, since bacteriologic studies are not usually made to identify individual members of the *Str. viridans* group. The strain isolated from this case proved to have a moderately high penicillin resistance.

With three negative blood cultures before discharge, presumably the infection was eradicated, but final conclusions regarding cure are not justified, since death from heart failure prevented a satisfactory period of observation. The rapid progression of heart failure after the institution of penicillin therapy in a patient digitalized and resting in bed, when previously he had not been receiving digitalis and had been moderately active, raises the question of the possible toxicity of penicillin for the myocardium. Electrocardiograms, however, failed to show any significant changes during treatment. Another possibility is that valvular changes from healing processes increased myocardial strain.

CASE 2 A 34-year-old housewife and secretary entered the hospital on September 1, 1944, with fever and malaise. There was no history of rheumatic fever. The illness had begun 16 months previously with a temperature of 104°F and generalized aching. Petechiae and a loud apical systolic murmur were found but repeated blood cultures were sterile. An

*From the Department of Internal Medicine, Lahey Clinic.

†Member, Department of Internal Medicine, Lahey Clinic.

‡Formerly fellow in internal medicine, Lahey Clinic.

intradermal test for undulant fever showed whealing, whereas agglutination tests for brucellosis were negative. There was no history of drinking of raw milk in recent years, and neighborhood herds of cows tested by the Vermont State Health Department were found free of Bang's disease. The blood sedimentation rate was 93 mm in 1 hour. A roentgenogram showed slight cardiac enlargement. A diagnosis of subacute bacterial endocarditis due to *Brucella abortus* was made, and the patient was given blood transfusions and injections of brucellergin. Only temporary improvement occurred, and sulfadiazine and arsenicals were unsuccessfully used. Intravenous injections of typhoid vaccine failed to cause a rise in temperature. Repeated blood cultures were sterile, and the sedimentation rate varied between 40 and 100 mm in 1 hour. Just before admission the patient had been

Few cases of bacterial endocarditis due to *Br. abortus* have been reported, and no satisfactory treatment has evolved. Trial with modern anti-bacterial substances failed in this case. Streptomycin appears to be of value in some cases of brucellosis,² but its final evaluation in this infection awaits future study, the drug was not available for use in this case.

No explanation is apparent for the isolation of five different bacterial species from the patient's blood. Mixed infection is not usually encoun-

FIGURE 1 Summary of Data in Case 1

given a total of 2,000,000 units of penicillin intramuscularly at intervals of 3 hours for 7 days.

On admission the patient did not appear ill, but she had lost 19 pounds. A loud apical systolic murmur was noted. There was no enlargement of the spleen or clubbing of the fingers. A gram-negative bacillus identified as *Br. abortus* was grown in four cultures, hemolytic *Staphylococcus aureus* on four, a diphtheroid on one and hemolytic and nonhemolytic staphylococci and gram positive bacilli on one, six cultures were sterile. The staphylococci were all coagulase negative and may therefore have been contaminants. Agglutination tests with the patient's serum and stock vaccines of *Brucella* organisms failed to show agglutination. The patient's serum agglutinated the isolated gram-negative bacilli in a titer of 1:5120. Urinalyses showed pyuria, and hemograms, a mild hypochromic anemia. A blood Hinton test was negative.

The following treatment failed to sterilize the blood stream: 400,000 units of penicillin intravenously daily for 19 days, sulfadiazine, which effected a blood level of 6 to 17.5 mg. per 100 cc. for 10 days, and sulfamerazine with a blood level of 11.2 to 15.8 mg. per 100 cc. for 12 days. The patient was discharged unimproved.

tered in bacterial endocarditis, and the question arises whether brucellosis predisposes to such a condition.

CASE 3 A 21-year-old housewife was first seen on July 25, 1944, because of dysuria and urinary frequency of 3 days' duration. A similar episode had occurred several months previously, and had responded to sulfonamide therapy. A cardiac murmur had been known to have been present since early childhood.

Physical examination disclosed a machine-like murmur and thrill over the pulmonic-valve area and cardiac enlargement to the left. The blood pressure was 120/40. Roentgenologic study revealed fullness of the left border of the heart in the region of the pulmonary conus. The transcardiac diameter was 13 cm., and the transthoracic 24.4 cm. The urine contained numerous pus cells, and a urogram showed a double ureter on the right. The urinary infection responded to sulfathiazole and subsided uneventfully. The patient was advised to have a right ureterectomy and ligation of the ductus arteriosus, but refused operation.

She remained well until 10 months later, when there developed fever, headache, arthralgia and myalgia, which did not respond satisfactorily to sulfadiazine administration at home, and on May 28, 1945, she was admitted to the hospital. In addition to the previous findings, she had a temperature of 100°F, herpes labialis and marked pallor. The blood pressure was 150/20. The blood sedimentation rate, previously normal, was 45 mm in 1 hour. Three blood cultures grew *Str. viridans*; one showed 28 colonies per cubic centimeter of blood. The circulation time was 25 seconds with Decholin and 8 seconds with ether. The venous pressure was equivalent to 80 mm of water. An electrocardiogram showed a diphasic T wave in Lead I and a prominent Q wave in Lead 3.

The patient was given 200,000 units of penicillin intramuscularly daily for 7 days, and the blood stream became sterile. Dr. Ralph Adams then ligated and resected the patent ductus arteriosus. Following operation, 40,000 units of penicillin was given intramuscularly every 3 hours for 3 weeks, and blood cultures remained sterile.

Shortly before discharge, roentgenographic studies showed the pulmonary conus to be less prominent, and the aortic arch to be slightly wider. An electrocardiogram revealed prominent Q waves in Leads 2 and 3 and increased voltage of the T waves in all leads. A faint systolic murmur persisted at the pulmonic area. The patient left the hospital on June 30.

A month later she was admitted to an out-of-town hospital because a blood culture had been found to contain a few colonies of *Str. viridans*, and although subsequent cultures were negative, a total of 4,000,000 units of penicillin was given. A letter from her physician reported her to be well and free of any signs of infection 22 months later.

It is not unusual for patients with a patent ductus arteriosus to develop blood-stream infection. Abbott³ found such a complication in 21 of 92 patients with this congenital heart lesion. Only recently has the combined use of surgical ligation and penicillin changed the fatal outcome. In suitable patients the best time to carry out operation is before infection has occurred, both to prevent subsequent endarteritis or endocarditis and to protect the heart from further strain. The largest series of cases is that of Gross,⁴ who reported successful division of the ductus arteriosus in 14 patients, 2 of whom had a superimposed *Str. viridans* endocarditis.

CASE 4. A 45-year-old silver-press foreman was admitted to the hospital on December 12, 1944. There was no history of rheumatic fever. Five months previously anorexia, weight loss, fever, chills and soreness of the fingertips had developed. Pneumonia was suspected, and treatment with sulfathiazole earned out. The patient improved, but the temperature continued to be elevated, spiking to 106°F. Numerous blood cultures and one bone-marrow culture were sterile. He was given penicillin in doses unknown to us for 18 days and is said to have shown improvement. No further therapy was used for the next 3 months.

On admission the patient appeared to be extremely ill. He had lost 20 pounds in weight. A café au lait color was noted. There was marked dental sepsis. A Grade III diastolic murmur heard in the left parasternal line was loudest in the 3rd costal interspace. Rales were detected in the lung bases. The fingers were clubbed, and the edge of the spleen extended 5 cm below the costal margin, but there were no petechiae.

Twelve blood cultures were sterile. A bone-marrow biopsy grew a nonhemolytic pleomorphic anaerobic streptococcus. Agglutination tests for undulant and typhoid fever gave negative results. Examination of the blood showed a mild hypochromic anemia, a normal number of leukocytes and a slight increase in the percentage of young cells. Urinalysis and a blood Hinton test were negative. X-ray examination disclosed that the heart was enlarged in all diameters, and the lungs were clear.

For 6 days the patient was given sulfadiazine to maintain a blood level of 12.8 to 14.8 mg per 100 cc., with dicumarol to reduce the prothrombin time of the blood to 48 to 77 per cent of normal. Three transfusions were given, and for the last 6 days of his life he received 400,000 units of penicillin daily by constant intravenous drip.

The fever remained intermittent, with peaks to 101°F. The murmur did not change until the day before death, when it was notably louder. The patient's condition continued to deteriorate uninfluenced by therapy, and he died 37 days after admission.

Autopsy. Post-mortem examination showed moderately sclerotic aortic cusps. The posterior cusp was torn at its left attachment to the aorta. Microscopically, there was fibrin at the tip of one of these cusps, and between the meshes of fibrin were leukocytes and a homogenous red substance. A Gram-Weigert stain was made, but no bacteria were identified. Near the base of one cusp there was an area about half the size of a low-power field filled with congested blood vessels and rather heavily infiltrated by polymorphonuclear leukocytes and lymphocytes. In the neighboring endocardium and sub-endocardium of the heart wall there was diffuse infiltration with polymorphonuclear leukocytes—in some places to the extent of forming small true abscesses. Other significant autopsy findings were congestive heart failure, extramedullary hematopoiesis and focal embolic glomerulonephritis.

This case represents the bacteria-free stage of bacterial endocarditis. Numerous blood cultures on special mediums failed to grow organisms, and special studies at autopsy failed to demonstrate bacteria. The significance of organisms isolated from the bone marrow is doubtful, for bacteria may lie dormant in the marrow for long periods with no relation to blood-stream infection.⁵ The fever in bacteria-free cases may be due to multiple small emboli similar to those found at autopsy in the kidney. Such a case is predestined to therapeutic failure with antibacterial substances, since bacteria are no longer responsible for the illness. It is possible that a prolonged period of anticoagulant therapy in these cases would prevent thrombi from forming on the heart valves and further embolization until healing had occurred.

CASE 5. A 42-year-old teacher entered the hospital on June 16, 1944, for decision regarding the need of further therapy. Two months before admission he had begun having gripe-like symptoms, elevations of temperature, occipital pains, paresthesias of the right arm and face and vomiting. He was hospitalized elsewhere, and blood cultures were taken. The thirteenth grew *Str. viridans*. One million one hundred thousand units of penicillin was given by constant intravenous drip from May 27 to June 4. Two days later the fever recurred, and urticaria appeared. Penicillin was again started, and from June 7 to June 16, a total of 28,000 units was given intramuscularly every 3 hours. Both the fever and the urticaria disappeared shortly after this second course had been instituted.

On admission the patient was asymptomatic. Early clubbing of the fingers was noted. The blood pressure was 120/70. A presystolic murmur and a snapping first sound were heard at the apex of the heart. There was no splenic enlargement, petechiae, dental sepsis or joint pains. The temperature and pulse remained normal.

Six blood cultures showed no growth. Urinalysis and a blood Hinton test were negative, and a hemogram, electrocardiogram and roentgenogram of the chest were normal. The blood sedimentation rate was 54 mm in 1 hour. No further treatment was deemed necessary.

In a follow-up letter 25 months after discharge a physician stated that the patient had remained perfectly well. There had been no sign of recurrence, but as an added precaution he had been hospitalized on three occasions at intervals of 6 months for a course of 1,000,000 units of penicillin.

It is noteworthy that the diagnosis was made early in this case. Although only moderate doses of penicillin over a relatively short time were used, the patient remained cured twenty-three months later. It is doubtful that the subsequent courses of penicillin were needed, since at no time was there any sign of recurrence. An interesting observation is the occurrence of urticaria shortly after the first course of penicillin, and its disappearance soon after institution of the second course. That the sedimentation rate of the blood does not determine cure is shown by its elevation even after cure had been established. Goerner, Geiger and Blake⁶ have reported its persistent elevation in some cases for more than six weeks.

CASE 6. A 57-year-old woman entered the hospital on May 10, 1944. In childhood she had had rheumatic fever. Six months before admission there had been fleeting joint pains and a low-grade fever that did not respond to salicylate therapy. Two blood cultures grew *Str. viridans*. In spite of satisfactory concentrations of sulfadiazine in the blood, cultures remained positive, temperature elevations continued and occasional petechiae were found.

Physical examination disclosed a *cafe au lait* color, a rim of fine new pink skin at the nail bases, indicative of early clubbing, a systolic murmur at the apex heard only in the left lateral position, an accentuated apical first sound, carious teeth, a tender, red swelling of the left instep and tenderness of the right elbow. The patient had lost several pounds in weight but did not appear acutely ill. There was no splenic enlargement, and the lungs were clear. Roentgenograms of the chest showed no cardiac enlargement. The blood sedimentation rate was 79 mm in 1 hour. Blood cultures grew *Str. viridans*. Urinalyses were negative, and hemograms normal.

One million units of penicillin was given by constant intravenous drip during the next 10 days, followed by 12,500 units intramuscularly every 3 hours for another 10 days. There was clinical improvement, with remission of the fever and disappearance of the joint pains. The heart murmur increased in intensity. The sedimentation rate dropped to 48 mm in 1 hour, and the patient was discharged.

Shortly after her return home she suffered a relapse that was treated with 2,000,000 units of penicillin. A report, 24 months later, stated that she was perfectly well.

This patient was the first to be treated with penicillin at the clinic, and supplies were scarce. The successful outcome, like that in Case 5, proves that an occasional patient with bacterial endocarditis responds satisfactorily to small doses of penicillin given over a relatively short time. Nevertheless, now that penicillin is plentiful, large doses over a long period should be used to allow a good margin of safety. If relapse occurs, further treatment may be successful, as in this patient. The change in the intensity of the heart murmur under treatment suggests structural change in the valve as a result of healing of the infected cusps.

CASE 7. A 32-year-old machinist was admitted to the hospital on December 29, 1944, because of polydipsia, polyuria, fever, chills, diarrhea and malaise of 7 days' duration. In 1934 he was said to have had hematuria and similar symptoms. Blood cultures taken elsewhere were reported to have grown gram-positive staphylococci and streptococci. A total of 470,000 units of penicillin had been given intramuscularly by a physician.

Physical examination revealed no signs of bacterial endocarditis other than petechiae. A chest roentgenogram was normal. The urine contained a trace of albumin, and the sediment showed occasional red and white cells. Examination

of the blood was negative, except for a white-cell count of 12,500. The blood sedimentation rate was 100 mm in 1 hour. A blood culture taken soon after admission showed a coagulase-positive *Staph. aureus*.

The patient was given 20,000 to 30,000 units of penicillin intramuscularly every 2 hours, and 2,420,000 units was administered during the next 32 days. The temperature varied from 99 to 103.6°F, and the urine continued to show blood cells and casts. The white-cell count remained between 10,000 and 20,000. The heart sounds remained normal until January 6, when a systolic murmur and thrill were found in the aortic area, and a diastolic murmur over the entire precordium. Three days later the patient developed acute pulmonary edema, which responded to atropine. On January 20 a pericardial friction rub was heard, 2 days later he developed pulmonary edema and died.

Autopsy. The significant findings included subacute bacterial endocarditis of the aortic valve, cardiac hypertrophy and dilatation, serofibrinous pericarditis, a recent splenic infarction, acute glomerular nephritis and congestive heart failure. Microscopical examination of firm, white nodules from the aortic valve showed fibrosis, hyalinization and infiltration by leukocytes, with a predominance of polymorphonuclear cells.

The custom of calling bacterial endocarditis acute if it has been present for less than six weeks and subacute after it has persisted six weeks or longer has less significance than heretofore. In cases that would formerly have been called subacute, penicillin often arrests the illness before it has lasted six weeks, and may prolong the course of the acute type beyond this period. A better way of classifying bacterial endocarditis is by indication of the causative organism, as in pneumonia. This case exemplifies the difficulty of distinguishing acute from subacute disease, since the clinicians considered it acute whereas the pathologists thought it subacute. We have preferred to classify it as bacterial endocarditis due to *Staph. aureus*.

CASE 8. A 28-year-old housewife entered the hospital on October 10, 1945. She had had rheumatic fever in childhood and again at the age of 22. Seventeen months before admission, she had had a sore throat and cystitis, both of which had responded rapidly to sulfonamide therapy, but malaise and a low-grade fever had continued. In August there were migratory joint pains and petechiae. Repeated blood cultures were positive for *Str. viridans*. Penicillin, heparin and sulfadiazine were administered unsuccessfully, and for 11 months the patient gave herself 15,000 units of penicillin intramuscularly every 3 hours day and night. In March a sharp pain in the left lumbar region was diagnosed as renal infarction, and in May a chest pain was called pulmonary embolism. Blood cultures remained positive, but the fever well and for 2 months before admission remained afebrile. On the day before entry she experienced a severe bilateral headache with nausea and vomiting. Cerebral embolism was suspected.

Physical examination disclosed a well nourished woman whose weight had been increasing slightly and who did not appear acutely ill. Significant findings were a temperature of 101°F, cardiac enlargement, an apical systolic murmur widely transmitted, a diastolic murmur over the left 3rd and 4th costochondral junctions and *Str. viridans* on blood culture. There were no petechiae, finger clubbing or splenic enlargement. A spinal puncture demonstrated normal dynamics of the fluid, with 297 polymorphonuclear leukocytes per cubic millimeter, a culture of the fluid was sterile. The headache disappeared after this examination, and late specimens of spinal fluid showed no leukocytosis.

Urinalyses showed a trace of albumin, and hemograms, mild hypochromic anemia, a blood Hinton test was negative. The blood sugar and nonprotein nitrogen determinations were normal.

Three hundred thousand units of penicillin was given by constant intravenous drip daily for 6 days, 200,000 units for 3 days, and 320,000 units for 2 days. A sulfadiazine blood level of 9.1 mg per 100 cc. was maintained for 12 days. On discharge the patient was instructed to take 15,000 units of penicillin intramuscularly every 3 hours.

One week later two or three colonies of *Str. viridans* per cubic centimeter of blood were found, and an additional 3,000 units of oral penicillin every 3 hours was prescribed. A few days later the temperature rose to 100.8°F and there were fresh petechiae so that 1 gm of sulfadiazine every 4 hours was added.

The patient re-entered the hospital on November 21, and was given 500,000 units of penicillin daily by constant intravenous drip for the next 5 weeks. Three blood cultures were negative before discharge on December 28. She continued to give herself 25,000 units of penicillin intramuscularly every 3 hours. Blood cultures remained sterile, but the blood sedimentation rate continued to be elevated and a low-grade fever persisted. On July 10, 1946, when last examined, she had gained 15 pounds in weight and felt well. The blood sedimentation rate was 66 mm in 1 hour. Approximately 100,000,000 units of penicillin had been given during the previous 19 months.

Therapy with relatively large doses of penicillin for five weeks and with moderate doses for seventeen months failed to bring about a cure, although such treatment suppressed the infection and prevented symptoms.

Why this particular infection was so refractory to penicillin has not yet been determined since the organism was not fully identified, nor was its penicillin sensitivity studied when first isolated. At present, blood cultures are negative, and these studies cannot be made. If these investigations were made routinely at the outset in every case, information would be on hand to help explain such resistant infections. Plans are being made to administer massive doses of penicillin combined with fever therapy to this patient over a prolonged period.

CASE 9 A 40-year-old executive entered the hospital on February 23, 1944. He complained of lack of energy, occasional vomiting, a weight loss of 30 pounds and intermittent elevations of temperature to 101°F during the previous 4 months.

Physical examination revealed a systolic murmur at the apex and a to-and-fro murmur at the aortic area. The blood pressure was 130/60. The temperature was 100°F. Early clubbing of the fingers was present. A blood culture grew one or two colonies of *Str. viridans* per cubic centimeter of blood. The urine showed a trace of albumin, and the sediment contained occasional casts and white cells. Examination of the blood was negative, the blood sedimentation rate was 79 mm in 1 hour. Agglutination tests for typhoid and Brucella infections were negative. An electrocardiogram showed only left-axis deviation. X-ray studies showed prominence of the heart to the left, apical infection of several teeth and normal sinuses and lungs.

Bacterial endocarditis was diagnosed and 12 gm of sulfadiazine was given daily for 9 days in combination with four hours of artificial fever from typhoid vaccine. Three subsequent blood cultures were sterile. Tonsillectomy and extraction of the infected teeth were done, and the patient was discharged on April 8.

A blood culture taken on the day of discharge later showed five or six colonies of *Str. viridans*, and the patient was advised to take 4 gm of sulfadiazine daily under the supervision of his physician since no penicillin was available. Two blood cultures during May were positive.

The patient was readmitted to the hospital on June 15 and given 100,000 units of penicillin intravenously daily for 10 days and 200,000 units intramuscularly for 5 days. Soon after

discharge his physician gave him another 1,000,000 units intramuscularly.

He remained well. No evidence of infection was found when he was again hospitalized 5 months later for study. As an added precaution he was given 12,500 units of penicillin intramuscularly every 3 hours for 10 days. Twenty-two months after the original penicillin treatment, his condition was still satisfactory.

The rate of progression of cardiac damage is not predictable in bacterial endocarditis. In Cases 1, 4 and 7 valvular or myocardial injury rapidly led to heart failure, whereas in Case 9 no further cardiac damage was apparent even after nine months of infection.

* * *

As demonstrated in Table 1, there was bacteriologic arrest in 7 cases and persistence of infection in 2. Of the former, 4 patients are living and well twenty-four, twenty-three, twenty-two and ten months later, respectively, and 3 died with no signs of bacterial infection. Two died from congestive heart failure, and 1 from rupture of an aortic-valve cusp. In all fatal cases repeated blood cultures before death were sterile. Autopsy was performed in 2 cases, and no organisms were demonstrated. Since it has been shown that relapses usually occur within thirty days of cessation of treatment and are rare after fifty days,⁷ we consider ourselves justified in regarding the surviving patients as cured. Of the bacteriologic failures, one was due to *Br. abortus*, and the other to unknown factors.

Dental sepsis was present in 3 patients. There was none in 2, and in 4 the condition of the teeth was not stated. Infected teeth have long been suspected of being a portal of infection in bacterial endocarditis. Transient bacteremia followed tooth extraction in 75 per cent of 40 persons with marked pyorrhea and in 34 per cent of 38 persons with no dental infection.⁸ Also, a number of cases have been recorded in which tooth extraction seemed to cause the bacterial endocarditis.⁹ On the other hand, dental sepsis has been secondary to emboli lodging in the dentine cavity,⁹ so that the role of dental infection in bacterial endocarditis is difficult to evaluate.

Other portals of infection frequently mentioned are the sinuses and gastrointestinal tract. We have seen no suggestion that the genitourinary tract is also a site for the invasion of organisms in bacterial endocarditis. In 4 cases pyuria was present, and there is a patient in the hospital who had a history of pyuria for four years and developed enterococcal endocarditis following resection of a contracted bladder outlet.

The sedimentation rate of the blood was abnormally high in all cases in which it was determined. In Case 5 it was increased to 54 mm in 1 hour a week after the administration of penicillin had been stopped and cure established. Others have found the sedimentation rate to remain elevated for

It is noteworthy that the diagnosis was made early in this case. Although only moderate doses of penicillin over a relatively short time were used, the patient remained cured twenty-three months later. It is doubtful that the subsequent courses of penicillin were needed, since at no time was there any sign of recurrence. An interesting observation is the occurrence of urticaria shortly after the first course of penicillin, and its disappearance soon after institution of the second course. That the sedimentation rate of the blood does not determine cure is shown by its elevation even after cure had been established. Goerner, Geiger and Blake⁶ have reported its persistent elevation in some cases for more than six weeks.

CASE 6 A 57-year-old woman entered the hospital on May 10, 1944. In childhood she had had rheumatic fever. Six months before admission there had been fleeting joint pains and a low-grade fever that did not respond to salicylate therapy. Two blood cultures grew *Sir viridans*. In spite of satisfactory concentrations of sulfadiazine in the blood, cultures remained positive, temperature elevations continued and occasional petechiae were found.

Physical examination disclosed a *cafe au lait* color, a rim of fine new pink skin at the nail bases, indicative of early clubbing, a systolic murmur at the apex heard only in the left lateral position, an accentuated apical first sound, carious teeth, a tender, red swelling of the left instep and tenderness of the right elbow. The patient had lost several pounds in weight but did not appear acutely ill. There was no splenic enlargement, and the lungs were clear. Roentgenograms of the chest showed no cardiac enlargement. The blood sedimentation rate was 79 mm in 1 hour. Blood cultures grew *Sir viridans*. Urinalyses were negative, and hemograms normal.

One million units of penicillin was given by constant intravenous drip during the next 10 days, followed by 12,500 units intramuscularly every 3 hours for another 10 days. There was clinical improvement, with remission of the fever and disappearance of the joint pains. The heart murmur increased in intensity. The sedimentation rate dropped to 48 mm in 1 hour, and the patient was discharged.

Shortly after her return home she suffered a relapse that was treated with 2,000,000 units of penicillin. A report, 24 months later, stated that she was perfectly well.

This patient was the first to be treated with penicillin at the clinic, and supplies were scarce. The successful outcome, like that in Case 5, proves that an occasional patient with bacterial endocarditis responds satisfactorily to small doses of penicillin given over a relatively short time. Nevertheless, now that penicillin is plentiful, large doses over a long period should be used to allow a good margin of safety. If relapse occurs, further treatment may be successful, as in this patient. The change in the intensity of the heart murmur under treatment suggests structural change in the valve as a result of healing of the infected cusps.

CASE 7 A 32-year-old machinist was admitted to the hospital on December 29, 1944, because of polydipsia, polyuria, fever, chills, diarrhea and malaise of 7 days' duration. In 1934 he was said to have had hematuria and similar symptoms. Blood cultures taken elsewhere were reported to have grown gram-positive staphylococci and streptococci. A total of 470,000 units of penicillin had been given intramuscularly by a physician.

Physical examination revealed no signs of bacterial endocarditis other than petechiae. A chest roentgenogram was normal. The urine contained a trace of albumin, and the sediment showed occasional red and white cells. Examination

of the blood was negative, except for a white-cell count of 12,500. The blood sedimentation rate was 100 mm in 1 hour. A blood culture taken soon after admission showed a coagulase-positive *Staph aureus*.

The patient was given 20,000 to 30,000 units of penicillin intramuscularly every 2 hours, and 2,420,000 units was administered during the next 32 days. The temperature varied from 99 to 103.6°F, and the urine continued to show blood cells and casts. The white-cell count remained between 10,000 and 20,000. The heart sounds remained normal until January 6, when a systolic murmur and thrill were found in the aortic area, and a diastolic murmur over the entire precordium. Three days later the patient developed acute pulmonary edema, which responded to atropine. On January 20 a pericardial friction rub was heard, 2 days later he developed pulmonary edema and died.

Autopsy The significant findings included subacute bacterial endocarditis of the aortic valve, cardiac hypertrophy and dilatation, serofibrinous pericarditis, a recent splenic infarction, acute glomerular nephritis and congestive heart failure. Microscopical examination of firm, white nodules from the aortic valve showed fibrosis, hyalinization and infiltration by leukocytes, with a predominance of polymorphonuclear cells.

The custom of calling bacterial endocarditis acute if it has been present for less than six weeks and subacute after it has persisted six weeks or longer has less significance than heretofore. In cases that would formerly have been called subacute, penicillin often arrests the illness before it has lasted six weeks, and may prolong the course of the acute type beyond this period. A better way of classifying bacterial endocarditis is by indication of the causative organism, as in pneumonia. This case exemplifies the difficulty of distinguishing acute from subacute disease, since the clinicians considered it acute whereas the pathologists thought it subacute. We have preferred to classify it as bacterial endocarditis due to *Staph aureus*.

CASE 8 A 28-year-old housewife entered the hospital on October 10, 1945. She had had rheumatic fever in childhood and again at the age of 22. Seventeen months before admission, she had had a sore throat and cystitis, both of which had responded rapidly to sulfonamide therapy, but malaise and a low-grade fever had continued. In August there were migratory joint pains and petechiae. Repeated blood cultures were positive for *Sir viridans*. Penicillin, heparin and sulfadiazine were administered unsuccessfully, and for 10 months the patient gave herself 15,000 units of penicillin intramuscularly every 3 hours day and night. In March a sharp pain in the left lumbar region was diagnosed as renal infarction, and in May a chest pain was called pulmonary embolism. Blood cultures remained positive, but she felt well and for 2 months before admission remained afebrile. On the day before entry she experienced a severe bilateral headache with nausea and vomiting. Cerebral embolism was suspected.

Physical examination disclosed a well nourished woman whose weight had been increasing slightly and who did not appear acutely ill. Significant findings were a temperature of 101°F, cardiac enlargement, an apical systolic murmur widely transmitted, a diastolic murmur over the left 3rd and 4th costochondral junctions and *Sir viridans* on blood culture. There were no petechiae, finger clubbing or splenic enlargement. A spinal puncture demonstrated normal dynamics of the fluid, with 297 polymorphonuclear leukocytes per cubic millimeter, a culture of the fluid was sterile. The headache disappeared after this examination, and later specimens of spinal fluid showed no leukocytosis.

Urinalyses showed a trace of albumin, and hemograms, a mild hypochromic anemia, a blood Hinton test was negative. The blood sugar and nonprotein nitrogen determinations were normal.

Three hundred thousand units of penicillin was given by constant intravenous drip daily for 6 days, 200,000 units for 2 days, and 320,000 units for 2 days. A sulfadiazine blood level of 9.1 mg per 100 cc was maintained for 12 days. On discharge the patient was instructed to take 15,000 units of penicillin intramuscularly every 3 hours.

One week later two or three colonies of *Str. viridans* per cubic centimeter of blood were found, and an additional 25,000 units of oral penicillin every 3 hours was prescribed. A few days later the temperature rose to 100.8°F and there were fresh petechiae, so that 1 gm of sulfadiazine every 4 hours was added.

The patient re-entered the hospital on November 21, and was given 500,000 units of penicillin daily by constant intravenous drip for the next 5 weeks. Three blood cultures were negative before discharge on December 28. She continued to give herself 25,000 units of penicillin intramuscularly every 3 hours. Blood cultures remained sterile but the blood sedimentation rate continued to be elevated, and a low-grade fever persisted. On July 10, 1946, when last examined, she had gained 15 pounds in weight and felt well. The blood sedimentation rate was 66 mm in 1 hour. Approximately 100,000,000 units of penicillin had been given during the previous 19 months.

Therapy with relatively large doses of penicillin for five weeks and with moderate doses for seventeen months failed to bring about a cure, although such treatment suppressed the infection and prevented symptoms.

Why this particular infection was so refractory to penicillin has not yet been determined since the organism was not fully identified, nor was its penicillin sensitivity studied when first isolated. At present, blood cultures are negative, and these studies cannot be made. If these investigations were made routinely at the outset in every case, information would be on hand to help explain such resistant infections. Plans are being made to administer massive doses of penicillin combined with fever therapy to this patient over a prolonged period.

Case 9. A 40-year-old executive entered the hospital on February 23, 1944. He complained of lack of energy, occasional vomiting, a weight loss of 30 pounds and intermittent elevations of temperature to 101°F during the previous 4 months.

Physical examination revealed a systolic murmur at the apex and a to-and-fro murmur at the aortic area. The blood pressure was 130/60. The temperature was 100°F. Early doubling of the fingers was present. A blood culture grew one or two colonies of *Str. viridans* per cubic centimeter of blood. The urine showed a trace of albumin, and the sediment contained occasional casts and white cells. Examination of the blood was negative, the blood sedimentation rate was 79 mm in 1 hour. Agglutination tests for typhoid and Brucella infections were negative. An electrocardiogram showed only left-axis deviation. X-ray studies showed prominence of the heart to the left, apical infection of several teeth and normal sinuses and lungs.

Bacterial endocarditis was diagnosed and 12 gm of sulfadiazine was given daily for 9 days in combination with four bouts of artificial fever from typhoid vaccine. Three subsequent blood cultures were sterile. Tonsillectomy and extraction of the infected teeth were done, and the patient was discharged on April 8.

A blood culture taken on the day of discharge later showed five or six colonies of *Str. viridans*, and the patient was advised to take 4 gm of sulfadiazine daily under the supervision of his physician since no penicillin was available. Two blood cultures during May were positive.

The patient was readmitted to the hospital on June 15 and given 100,000 units of penicillin intravenously daily for 10 days and 200,000 units intramuscularly for 5 days. Soon after

discharge his physician gave him another 1,000,000 units intramuscularly.

He remained well. No evidence of infection was found when he was again hospitalized 5 months later for study. As an added precaution he was given 12,500 units of penicillin intramuscularly every 3 hours for 10 days. Twenty-two months after the original penicillin treatment, his condition was still satisfactory.

The rate of progression of cardiac damage is not predictable in bacterial endocarditis. In Cases 1, 4 and 7 valvular or myocardial injury rapidly led to heart failure, whereas in Case 9 no further cardiac damage was apparent even after nine months of infection.

* * *

As demonstrated in Table 1, there was bacteriologic arrest in 7 cases and persistence of infection in 2. Of the former, 4 patients are living and well twenty-four, twenty-three, twenty-two and ten months later, respectively, and 3 died with no signs of bacterial infection. Two died from congestive heart failure, and 1 from rupture of an aortic-valve cusp. In all fatal cases repeated blood cultures before death were sterile. Autopsy was performed in 2 cases, and no organisms were demonstrated. Since it has been shown that relapses usually occur within thirty days of cessation of treatment and are rare after fifty days,⁷ we consider ourselves justified in regarding the surviving patients as cured. Of the bacteriologic failures, one was due to *Br. abortus*, and the other to unknown factors.

Dental sepsis was present in 3 patients. There was none in 2, and in 4 the condition of the teeth was not stated. Infected teeth have long been suspected of being a portal of infection in bacterial endocarditis. Transient bacteremia followed tooth extraction in 75 per cent of 40 persons with marked pyorrhea and in 34 per cent of 38 persons with no dental infection.⁸ Also, a number of cases have been recorded in which tooth extraction seemed to cause the bacterial endocarditis.⁹ On the other hand, dental sepsis has been secondary to emboli lodging in the dentine cavity,⁹ so that the role of dental infection in bacterial endocarditis is difficult to evaluate.

Other portals of infection frequently mentioned are the sinuses and gastrointestinal tract. We have seen no suggestion that the genitourinary tract is also a site for the invasion of organisms in bacterial endocarditis. In 4 cases pyuria was present, and there is a patient in the hospital who had a history of pyuria for four years and developed enterococcal endocarditis following resection of a contracted bladder outlet.

The sedimentation rate of the blood was abnormally high in all cases in which it was determined. In Case 5 it was increased to 54 mm in 1 hour a week after the administration of penicillin had been stopped and cure established. Others have found the sedimentation rate to remain elevated for

six weeks or longer after cure,⁶ and hence it is of no value as a guide for treatment or cure

Sterilization of the blood can be accomplished in the majority of patients with penicillin-sensitive organisms, but not in all. Geiger and Goerner¹⁰ recently reported a case in which infection persisted in spite of a sensitive organism, adequate penicillin, splenectomy and extraction of infected teeth. Other causes for failure in the treatment of bacterial endocarditis are complications from emboli or from the

rheumatic heart disease and 8 per cent with congenital heart lesions develop bacterial endocarditis.

Bacterial invasion of the blood stream is especially likely if a patient with a heart murmur complains of malaise, anorexia, weight loss or fever and if the sedimentation rate of the blood is elevated. We have encountered no case of bacterial endocarditis either in our series or in reviewing the recent literature — in which there was not an elevated sedimentation rate. The routine use of this test in

TABLE 1 Summary of Data in 9 Cases of Bacterial Endocarditis

CASE No	APPROXIMATE DURATION OF DISEASE BEFORE DIAGNOSIS mo	ORGANISM ISOLATED	THERAPY	REMARKS
1	6	<i>Str. viridans</i>	25 000 units of penicillin intramuscularly every 3 hr for 1 day 50 000 units of penicillin intramuscularly every 3 hr for 6 days 100 000 units of penicillin intramuscularly every 3 hr for 7 days 100 000 units of penicillin intramuscularly every 2 hr for 10 days	Patient died of heart failure. Cultures negative for 3 weeks before death.
2	16	<i>Br. abortus</i>	35 000 units of penicillin intramuscularly every 3 hr for 7 days 400 000 units of penicillin intravenously every day for 19 days Sulfadiazine blood level of 6.0–17.5 mg. per 100 cc. for 10 days Sulfamerazine blood level of 11.2–15.8 mg. per 100 cc. for 12 days	Case considered a therapeutic failure.
3	1½	<i>Str. viridans</i>	25 000 units of penicillin intramuscularly every 3 hr for 7 days 40 000 units of penicillin intramuscularly every 3 hr for 21 days Total of 4,000 000 units of penicillin 3 mo. later	Patient well 10 mo. later.
4	5	None*	400 000 units of penicillin intravenously every day for 6 days Dicoumarol for 6 days Sulfadiazine blood level of 12.8–14.8 mg. per 100 cc. for 6 days	Patient died of ruptured aortic valve, blood cultures negative, no evidence of infection at autopsy.
5	2	<i>Str. viridans</i>	160 000 units of penicillin intravenously every day for 7 days 28 000 units of penicillin intramuscularly every 3 hr for 9 days	Patient well 23 mo. later.
6	6	<i>Str. viridans</i>	100 000 units of penicillin intravenously every day for 10 days 12 500 units of penicillin intramuscularly every 3 hr for 10 days 2,000 000 units of penicillin later	Patient well 24 mo. later.
7	1½	<i>Staph. aureus</i> (coagulase positive)	30 000 units of penicillin intramuscularly every 2 hr for 4 days 20 000 units of penicillin intramuscularly every 2 hr for 17 days 30 000 units of penicillin intramuscularly every 2 hr for 11 days	Patient died of heart failure. Blood cultures negative for 3 wk. before death.
8	7	<i>Str. viridans</i>	15 000 units of penicillin intramuscularly every 3 hr for 10 mo. 300 000 units of penicillin intravenously every day for 6 days 200 000 units of penicillin intravenously every day for 2 days 320 000 units of penicillin intravenously every day for 2 days Sulfadiazine blood level of 9.1 mg. per 100 cc. for 12 days 15 000 units of penicillin intramuscularly every 3 hr for 14 days 25 000 units of penicillin orally every 3 hr for 7 days 500 000 units of penicillin intravenously every day for 35 days 25 000 units of penicillin intramuscularly every 3 hr for 7 mo.	Blood cultures negative, but signs of infection persist.
9	9	<i>Str. viridans</i>	100 000 units of penicillin intravenously every day for 10 days 25 000 units of penicillin intramuscularly every 3 hr for 5 days 1 000 000 units of penicillin later	Patient well for 22 mo.

*Diagnosis made on basis of clinical findings.

underlying heart disease, such as congestive heart failure, rupture of valve leaflets, perforation of the heart wall with cardiac tamponade, rupture of mycotic aneurysms or coronary occlusion, and from rupture of the spleen, massive pulmonary hemorrhage, focal nephritis with uremia, toxemia, cerebral embolism, reinfection with penicillin-resistant organisms and unrelated diseases.

Early Diagnosis

Owing to delay in diagnosis the organism becomes more firmly entrenched in a network of fibrin, with extension of damage to the heart valves, increased toxemia and complications from emboli. Such delay is frequent; it is not unusual for mild symptoms to be present for months before the diagnosis is even suspected. As many as 5 per cent of patients with

examination of patients with heart murmurs would be of value in selecting those needing further investigation. If patients with heart murmurs recorded their temperatures three times a day for one or two weeks whenever they noticed a change in their state of health, earlier suspicion would be aroused, leading to prompt study. A special search should be made for petechiae, Osler nodes, Janeway lesions, splinter hemorrhages beneath the nail bases, glossiness of the rim of the skin at the nail bases, indicative of early clubbing of the fingers,¹¹ splenomegaly and changes in the heart murmur. The rarity of bacterial endocarditis with auricular fibrillation is often mentioned as being of diagnostic value. In 286 cases of auricular fibrillation, however, it was found in 12.5 per cent,¹² so that

possibility of bacterial endocarditis must not be too readily dismissed because the heart is fibrillating

Bacteriologic Considerations

Streptococci belonging to the alpha-hemolytic group cause approximately 90 per cent of cases of bacterial endocarditis. Other organisms that have been found responsible include *Neisseria sicca*, *N. catarrhalis*, *N. gonorrhoeae*, *N. intracellularis*, *N. farosa*, *Diplococcus mucosus*, *D. crassus*, *Micrococcus ananrus*, *Gaffkyia tetragena*, *Staph. albus*, *Staph. aureus*, *Corynebacterium*, *Br. suis*, *Br. abortus*, *Br. melitensis*, *Spirillum surati*, *Streptobacillus moniliformis*, *Actinomyces necrophorus*, *Bacillus döderleinii*, *Haemophilus influenzae*, anaerobic hemolytic streptococci, enterococci, pneumococci and fungi such as *Monilia*, *Erysipelothrix*, *Leptothrix* and *Histoplasma*.

Str. viridans is often discussed as if it were an individual organism, but this is not so. It is a group of streptococci that produce a green pigment on blood agar, and includes *Str. salivarius*, *Str. equinus*, *Str. bovis* and its varieties and *Str. thermophilus*.¹⁴ Enterococci, notably *Str. faecalis*, may be mistaken for one of the viridans group unless special studies are undertaken. There has recently been reported isolation from cases of bacterial endocarditis of a *Str. viridans* that differs from other members of this group and has been designated by its discoverers *Streptococcus sbe*.¹⁵

It is not possible to compare the clinical course of infection arising from each of these streptococci, since they are rarely identified or reported. That there are differences is shown by the sensitivity to penicillin of some — for example, *Str. salivarius* — and the resistance of others, notably *Str. faecalis* and *Str. mulinaceous* (as in Case 1). With *Str. sbe*, the outlook is grave.¹⁵ The origin of the infection may be suggested by full identification, for some species inhabit the mouth, and some the intestinal tract, and others occur in animals or in milk products.

In obtaining blood for culture, at least 20 cc should be withdrawn, preferably following a chill when the fever is mounting. Pour plates are usually made with 0.5 cc., 1 cc. and 3 cc. of blood, and the rest is divided between two flasks, each containing at least 75 cc. of broth. Enriched mediums, such as hormone broth, heart-brain broth and tryptose-phosphate broth, are preferable since fastidious organisms, as well as others, will grow in them. Growth may be delayed, so that cultures should be incubated for at least ten days before being discarded. Repeated cultures are often necessary before the organism is isolated, for the bacteria may be present only intermittently in the blood stream. Para-aminobenzoic acid to neutralize sulfonamides and clarase to neutralize penicillin are sometimes added to the culture mediums, but in most cases the diluting effect of relatively large amounts of medium

is sufficient. If unusual infections are to be recognized, special bacteriologic examinations are necessary. In obscure cases, anaerobic cultural methods and special mediums, such as Sabouraud's medium, are required. Libman¹⁶ believes that positive cultures can be obtained in 84 to 95 per cent of cases, and in 1912 demonstrated organisms in the blood stream in 75 of 75 patients with bacterial endocarditis.

Treatment

Few investigators agree on optimal methods of treatment with penicillin. Differences of opinion exist regarding proper dosage, manner of administration, duration of therapy and use of anticoagulants, but almost all agree that the dose should be large and its administration prolonged. Some workers recommend an arbitrary dose of 500,000 units daily for five weeks.^{7, 17} Others individualize therapy, giving sufficient penicillin to raise the blood level five to ten times higher than that needed to inhibit growth of the organism.^{1, 18} The latter method is preferable, since organisms vary in their sensitivity to penicillin, and different blood levels are obtained from given amounts of penicillin. It may be necessary to give as much as 5,000,000 units daily, as in a patient now under treatment, to obtain effective concentrations in the blood. Increased penicillin resistance of the organism, although rare,¹⁹ may occur and remain undetected unless repeated sensitivity tests are done.

Administration by constant intravenous drip is generally considered superior to other methods, since higher and more constant blood levels are obtained.¹ Intermittent intramuscular injection is frequently employed. There does not appear to be any significant difference in the percentage of cures by either method if sufficient penicillin is used.

Anticoagulant therapy is not generally used in conjunction with penicillin, since complications are frequent and the end results do not appear to be improved. For patients who do not respond to penicillin, however, it may have a place. Loewe¹ reported 2 cases and mentioned 5 others in which the combined treatment was required to achieve cure.

Bacteriophage was found by MacNeal²⁰ to contribute to the cure of a patient with enterococcal endocarditis. In view of the poor prognosis in this type of infection, further trials with bacteriophage are warranted. Surgery has become increasingly important in treating bacterial endocarditis not only for eliminating foci of infection but also for correcting congenital cardiac anomalies. To our knowledge, no one has reported the use of artificial fever as an adjunct to penicillin therapy of bacterial endocarditis. Its possible value is suggested by the improvement in results with the sulfonamides when fever therapy was added.¹⁸

Congestive heart failure may occur during the treatment of bacterial endocarditis, and measures

to forestall this complication should be instituted. Frequently, the patient should be digitalized, activity markedly restricted, and sodium prohibited. Five per cent glucose in distilled water, rather than physiologic saline solution, should be used for the intravenous administration of penicillin. The amount of sodium in sodium penicillin need not be considered, for in 1,000,000 units there is approximately 167 mg of the sodium ion, equivalent to the amount in about 20 cc of physiologic saline solution.²¹

SUMMARY

Nine cases of bacterial endocarditis are reported in which penicillin failed to sterilize the blood stream in only 2.

Earlier diagnosis would be possible if the presence of bacterial infection were questioned in all patients with heart murmurs, if such patients were instructed to record their temperatures whenever a change in health occurred and if the blood sedimentation rate were determined routinely at examinations. A plea is made for more detailed bacteriologic study of causative organisms, and especially for the identification of alpha-hemolytic streptococci.

Treatment may be carried out with arbitrary doses of penicillin, but basing doses on penicillin sensitivity studies and determinations of blood levels ensures the administration of adequate amounts. Five weeks of therapy is generally considered satisfactory. Therapeutic failure is more frequently the result of complications from the underlying heart disease than of the infection, therefore, the

importance of early diagnosis, before complications arise, is emphasized.

PERSISTENCE OF REMISSIONS OF THYROTOXICOSIS AFTER CESSATION OF THIOURACIL THERAPY*

ROBERT H WILLIAMS, M D,† SAMUEL P ASPER JR M D,‡ WALTER F ROGERS, JR, M D,‡
JACK D MYERS, M D,‡ AND CHARLES W LLOYD M D ‡

BOSTON

THE great effectiveness of thiouracil and related compounds in controlling thyrotoxicosis has been well established. In most cases this type of therapy can be continued for many months or years without the production of ill effects or a state of refractoriness. One cannot be certain, however, that undesirable metabolic abnormalities will not develop after long intervals of therapy. For this reason, as well as others, it is important to determine the optimal treatment necessary to produce remissions that will be sustained after cessation of thiouracil therapy. Only a few results dealing with this subject have been reported.¹⁻⁷ Approximately a year ago it was found that of 100 patients with thyrotoxicosis treated with thiouracil, 49 were in a remission for intervals of three to twenty-one months following the discontinuance of treatment.⁶ These studies have been extended and are the basis of this report.

The types of cases treated, the outline of therapy and the nature of the follow-up examinations have previously been presented.⁶ So far as the selection of cases for treatment without thyroidectomy is concerned, the only factor that appears to be significant is that few patients with thyroid glands more than five times the normal size were treated.

This report presents the results in all patients who had a cessation in thiouracil therapy, including the cases in which the patient stopped treatment of his own accord. Seven patients disappeared from the clinic during their second or third course of therapy and were not heard from in spite of repeated solicitations. All of these are included in the group experiencing relapses of the disease, but it is possible that some of them are now in remission. Several of the other patients, especially the ones with sustained remissions, would probably have disappeared from observation had it not been for special requests for their return.

On cessation of thiouracil therapy the patients were given a clinical examination and a test of basal metabolic rate at monthly intervals for four months, bimonthly until the end of a year and then at intervals of from three to six months.

Of the 111 patients who were treated with thiouracil or one of its derivatives and had a discontinuation of therapy, 47 have had no evidence of re-appearance of thyrotoxicosis, although they have not received any treatment for intervals of from three to thirty-one months. In addition, 4 patients, after receiving a second course of thiouracil therapy, have experienced a sustained remission for intervals of from five to thirteen months. Thus, 51 of the 111 patients, or 46 per cent, appear to need no more treatment. Indeed, 44 have been free of thyrotoxicosis for more than a year after cessation of therapy, and 33 have remained well for more than eighteen months (Fig 1). Moreover, of the patients who have been well for more than a year without treatment, only 1 has had a relapse of the thyrotoxicosis. Most of the patients who had a relapse had it within a few months. 70 per cent had it within two months, and 88 per cent within five months. One patient, however, had a relapse after having been well for thirteen months without treatment.

Many of the patients who experienced relapses were treated again with thiouracil. Of 12 who have again had a cessation of therapy 4 have had a persistent remission, but 8 have had another relapse. Four of the 8 patients, however, were treated for less than six months in the second course of therapy.

Only 4 of 21 male patients, or 18 per cent, had a sustained remission, whereas 47 of 90 female patients, or 52 per cent, remained well. Those experiencing a decrease in the size of the thyroid gland while receiving thiouracil treatment were more prone to have a sustained remission of the disease than the ones whose glands increased in size or showed no change. Patients with small goiters or slight thyrotoxicosis experienced a more persistent response than the ones with large goiters or severe thyrotoxicosis. Factors that did not seem to be of much significance in obtaining a persistent remission were the age of the patient, the duration of the disease and the nodularity of the thyroid gland. The duration of therapy was of distinct significance, but varied a great deal in different cases. In fact, none of the 3 patients treated continuously for the longest interval remained well (Fig 2).

In a consideration of the correlation of the duration of treatment with sustained remissions of

thyrotoxicosis that were obtained, it is to be borne in mind that the prolonged course of therapy in some cases was due to the suggestion by the clinical course of the patient that a relapse would probably result if the therapy were discontinued. The deci-

FIGURE 1 Duration of Sustained Remissions

All the patients included in this chart are in a state of euthyroidism at present. Thus far, none of our patients, except one who has been free of thyrotoxicosis for a year, have had a re-appearance of this disease.

sion regarding when treatment was to be discontinued was, in part, based on the maintenance dose of thiouracil that was required.

Nine patients were treated with thiouracil during pregnancy for a month or longer. Three were treated for several months before fertilization, with continued therapy throughout pregnancy. The thyrotoxicosis was well controlled. No infants were found to have a goiter or a disturbance in thyroid function at birth or during the interval of more than a year that they have been followed.

Of 9 female patients with malignant exophthalmos, 5 have had a remission that has persisted after cessation of therapy. None of the 4 male patients with this disturbance, however, have remained well.

In none of the more than 300 patients that we have treated with thiouracil or one of its derivatives has carcinoma of the thyroid gland been found, although some patients have received one of these drugs most of the time for three years. Moreover, in the majority of cases treated for eight months or longer, the thyroid gland was found to have decreased in size or not to have shown any essential change.

No untoward effects, other than the types of toxic reactions that have been observed with short intervals of thiouracil therapy, have been demonstrated in the patients given this compound for a year or longer. Such complications, however, must continue to be considered.

The following brief résumés of some of the case reports are presented to indicate the nature of the problems and the results obtained.

Cases with Persistent Remissions

CASE 21 A 36-year-old Negress, during the 13 months before admission, had observed nervousness, hyperhidrosis, heat intolerance, weakness, fatigue, goiter, hyperorexia, a loss of 35 pounds in weight, palpitation, dyspnea and slight

exophthalmos. Physical examination revealed a moist, hot skin, a tremor, a pulse rate of 120, slight exophthalmos, diffuse enlargement of the thyroid gland to approximately two and a half times the normal size and a loud bruit. The basal metabolic rate was above +80 per cent on two occasions, and the protein-bound iodine was 14 microgm per 100 cc of plasma. With no treatment other than thiouracil, the basal metabolic rate became normal within 2 months and has subsequently remained normal for 32 months, although no treatment has been given for the last 17 months. The patient regained all the weight that she lost and has felt well in every way.

CASE 31 A 32-year-old Negress stated that for 5 months before hospitalization she had been bothered by nervousness, weakness, fatigue, hyperorexia followed by anorexia, diarrhea, a loss of 50 pounds in weight, palpitation, tachycardia, dyspnea, orthopnea, edema of the legs, hyperhidrosis and heat intolerance. Physical examination disclosed congestive heart failure, with a pulse rate of 110, a warm, moist skin, a tremor, marked exophthalmos, nodular enlargement of the thyroid gland to three times the normal size and a loud bruit. The basal metabolic rate was +64 per cent, but 1 month after the beginning of thiouracil therapy it was normal. This drug was given continuously for 18 months, during the last 9 of which the patient was pregnant, giving birth to healthy twins. The dosage of thiouracil during the last

FIGURE 2 Interval of Continuous Treatment

The percentage of sustained remissions does not appear to be particularly affected by the duration of therapy. In some cases, however, the duration of the therapy was governed by the response of the patients while they were receiving thiouracil.

5 months of pregnancy was 0.2 gm daily. Although therapy has been discontinued for 18 months, the patient has remained in excellent condition. She has gained a total of 85 pounds, and the thyroid gland seems to be normal in size, shape and consistency.

CASE 77 A 35-year-old woman had had moderately severe thyrotoxicosis of 5 months' duration, malignant exophthalmos, diffuse enlargement of the thyroid gland to approximately one and three quarter times the normal size and elevation of the basal metabolic rate to +55 per cent. The response of the thyrotoxicosis to thiouracil was slow, no more than 0.4 gm daily of this compound was used because of the malignant exophthalmos. In spite of this precaution, the ophthalmopathy became worse, so that treatment with desiccated thyroid was begun. Thereafter, the eyes and the thyrotoxicosis showed slow improvement. Thiouracil was given for 11 months and was then discontinued, as was the desiccated thyroid. The patient has been free of hyperthyroidism for 18 months subsequently, and during this interval she went through a normal pregnancy. The exophthalmos has improved slightly.

CASE 99 The patient was a 51-year-old unmarried woman who had moderately severe thyrotoxicosis that had begun 2 months before treatment with thiouracil. The basal metabolic rate decreased from +62 per cent to -9 per cent after treatment for 5 weeks. Therapy was continued for 11 months

The patient has remained in excellent condition in spite of the cessation of treatment 18 months ago. The thyroid gland, which was two and a half times the normal size before treatment, is about one and three quarters times normal.

Case 154. A 28-year-old Finnish woman had had thyrotoxicosis for 1 year. The lowest basal metabolic rate preceding treatment had been +51 per cent, and the rate became normal within 4 weeks after thiouracil therapy was started. The treatment was continued for only 6 months, but the patient has remained entirely well for 21 months subsequently. During that time she has gone through a normal pregnancy. The thyroid gland, which was estimated to be one and three quarters times the normal size before therapy, seems to be normal in every respect.

Case 178. A 63-year-old woman with thyrotoxicosis of 3 months' duration was found to have a basal metabolic rate of +47 per cent. Within 4 months of treatment with thiouracil, the metabolic rate was normal. This therapy was given for a total of 8 months and was discontinued, but the patient has remained well for 14 months subsequently. The thyroid gland, which was about one and a third times the normal size before treatment, is normal.

Cases with Relapses

Case 2. A 55-year-old painter had had symptoms of thyrotoxicosis for 1 year. The disease was severe and was associated with heart failure and malignant exophthalmos. The thyroid gland was about three times the normal size. The basal metabolic rate was +84 per cent. Within 4 weeks after thiouracil therapy was started, the basal metabolic rate was normal. After treatment was given for 5 months, the patient failed to return to the clinic, in spite of repeated requests. Seven months later, he returned in a condition that was almost as poor as that at the beginning of treatment. With thiouracil therapy, the basal metabolic rate became normal after 10 weeks. This course of treatment was continued for 10 months, but the patient had a relapse 1 month thereafter. A third course of thiouracil therapy was started, but the patient disappeared after it had been given for 2 months.

Case 4. A 49-year-old female factory worker had had thyrotoxicosis for 22 years. During the early phase of the illness she had been subjected to three thyroid operations. She had taken Lugol's solution periodically for 22 years. The basal metabolic rate was +56 per cent, and the thyroid gland was about two and a half times the normal size. She showed an adequate response to thiouracil, but this therapy was given continuously for 20 months. She remained in excellent condition for 4 months after cessation of therapy but developed a relapse during the subsequent month. Potassium iodide did not cause a complete response. Thiouracil, in amounts of 0.2 gm daily, was then given, but the patient developed agranulocytosis. Thereafter she was treated satisfactorily with radioactive iodine.

Case 5.* A 35-year-old housewife had had mild thyrotoxicosis for 1 year. The basal metabolic rate was +45 per cent, and the thyroid gland was two and a half times the normal size. The disease was readily controlled with thiouracil, and the basal metabolic rate finally decreased to -25 per cent under a maintenance dose of 0.1 gm every 2 days. This therapy was given for 11 months and then discontinued. The patient, however, had a relapse 6 weeks later. On resumption of thiouracil therapy a febrile reaction occurred, a similar reaction followed tetramethylthiourea. Potassium iodide was then given, but within 3 days a violent bullous eruption developed. This therapy was discontinued, and the patient was then treated satisfactorily with radioactive iodine.

Case 14. A 52-year-old railroad fireman with severe thyrotoxicosis of 3 months' duration had a thyroid gland that was three times the normal size and a basal metabolic rate of +64 per cent. He showed a standard response to treatment with thiouracil, the dosage in this case was initially about 1 gm. daily, as was that in the other cases at this early stage of development of thiouracil therapy. After the

patient had been treated for 4 months, the thyroid gland had increased to six times the normal size, but with 2000 r of x-ray therapy over the gland, it decreased to its original size. Thiouracil treatment was discontinued after it had been given continuously for 19 months. The patient remained in good condition for 2½ months but then had a relapse. Another remission was readily induced with 6-methylthiouracil and was maintained with potassium iodide, which was given for 4 months. Three months after cessation of this therapy, a relapse occurred. Another remission was produced within 3 weeks, 6-butylthiouracil therapy being employed. Potassium iodide was then used as the only treatment for 6 weeks. A relapse occurred 4 months after the iodide had been stopped. Radioactive iodine is now to be used.

Miscellaneous Cases

One patient has taken thiouracil most of the time for three years. Of her own volition, she stopped the treatment five times, on each occasion she permitted a lapse of about two months without therapy, and each time a relapse occurred within about a month. A patient who had taken thiouracil continuously for eighteen months had a relapse within a month after stopping treatment. A second course of therapy was given for nine months, consisting of thiouracil for the first two months and potassium iodide for the last seven. She has remained in excellent condition for ten months following the cessation of antithyroid treatment. Another patient† received thiouracil for eight months and had a remission that persisted for ten months after therapy had been stopped. She then had a relapse, which was treated for a month with ethyl-diiodobromate⁹, a remission has been present for eight months. Still another patient,† treated with thiouracil for six months, had a remission lasting six months after treatment was stopped. Although a moderately severe relapse occurred, she responded well to para-aminobenzoic acid, obtaining a remission that has lasted for eight months since the cessation of therapy. One patient who was receiving desiccated thyroid for hypometabolism at the time she developed thyrotoxicosis not only had a remission of the Graves's disease that has lasted for twenty-eight months but also again developed hypometabolism with a basal metabolic rate of -27 per cent. One patient has received tetramethylthiourea, thiouracil or propylthiouracil continuously for twenty months, because on the basis of the maintenance doses necessary, it is apparent that a relapse would soon take place if treatment were to be stopped. In another case, in which the course was similar after the administration of thiouracil continuously for a year, radioactive iodine was given, since a sustained remission did not appear promising with thiouracil therapy. In 3 similar cases the thiouracil treatment was discontinued to ascertain whether a remission would result, but in each a relapse developed within a month.

DISCUSSION

The results presented above indicate that thiouracil or related compounds can be used alone in the control of many cases of thyrotoxicosis. This raises the question whether thiouracil derivatives, radioactive iodine or thyroidectomy should be prescribed in most cases of thyrotoxicosis. This query can be better answered when more is learned about the possible ill effects of the newer types of treatment. On the basis of the present results, however, it appears unnecessary to perform a subtotal thyroidectomy in many cases of thyrotoxicosis. In patients with large nodular goiters and those with pronounced compression of the trachea or esophagus, thyroidectomy is indicated, but essentially all the other cases can be treated with antithyroid drugs or radioactive iodine 5-10.

*This case was reported by Chapman and Evans⁸ in 1946 (Case 16).

†These cases are included in the group with relapses and not in that with persistent remissions.

Carcinoma of the thyroid gland occurs so rarely in patients with thyrotoxicosis that the routine removal of the gland as a prophylactic measure does not seem justified.¹¹ There is a possibility that thyroid carcinomas are associated with radioactive iodine or thiouracil therapy, but there is no evidence of such an association.

There is also a possibility that radioactive iodine will produce damaging effects to tissues other than the thyroid gland, especially the kidneys, but no such ill effects have been demonstrated in any patient. The main handicap in depending on radioactive iodine, aside from its scarcity, is in estimating the dosage that is required. Excessive doses may produce myxedema, whereas inadequate amounts may not control the thyrotoxicosis. If the dosage of radioactive iodine is insufficient, however, additional doses can be given, or the patient can be treated with one of the thiouracils.

The newer thiouracils, especially 6-propylthiouracil and 6-cyclopropylthiouracil,^{9, 12} can be used with relative safety, and it seems to be safe to dispense them widely. With this type of therapy the basal metabolic rate can be adjusted to the desired level. Moreover, with increased experience with these compounds, the frequency with which the patients must consult the physician can be greatly reduced. Whether the incidence of remissions will be the same as that with thiouracil is not known, although this appears probable. In most patients with thyrotoxicosis it appears desirable to use propylthiouracil for about nine months, or longer, before any other treatment is given. If a relapse occurs, some of the patients can be treated with radioactive iodine, and the others with additional courses of propylthiouracil.

The duration of continuous thiouracil therapy is important. It is believed that in most cases the drug should be given for nine to fifteen months. This interval is arbitrary in some cases, but in others it is indicated by the clinical course of the patient. Patients who continue to require more than 50 mg of thiouracil daily, those with thyroid glands that enlarge even though no hypothyroidism exists, those with increasing manifestations of malignant exophthalmos and those with a loud bruit over the thyroid gland usually need to be treated for a longer interval. On the other hand, the therapy can be stopped in patients who have been in good condition for several months even with a daily dosage of thiouracil of 50 mg, the ones whose thyroid glands have decreased in size during therapy, those with no bruit over the thyroid gland and those who maintain a normal metabolic rate in spite of distressing situations. The manifestations of thyrotropic activity thus appear to be important aids in regulating the duration of therapy.

No criteria have been found that enable an accurate prediction of just which patients will develop a remission that will persist after cessation

of thiouracil therapy, but a few factors are known to have some influence on the course of the disease. On the basis of the results presented above, it appears that the majority of female patients with small goiters and mild thyrotoxicosis experience a remission of the disease that persists after cessation of thiouracil therapy, the results are not so good if the thyrotoxicosis is severe, if the goiter is large or if the patient is a male. The duration of the disease preceding therapy, the age of the patient and the nodularity of the gland do not appear to influence the incidence of remissions, but as larger series of cases are analyzed and as an opportunity is afforded to control some of the variable characteristics, these factors will probably be found to affect the prognosis.

Contrary to the impression of others,⁷ we do not believe that nodular goiters contraindicate prolonged thiouracil therapy. Moreover, in this clinic, pregnancy has not been a contraindication to thiouracil therapy. In fact, patients who are found to have thyrotoxicosis during pregnancy can possibly be treated more safely with propylthiouracil than with radioactive iodine or by thyroidectomy. It is essential, however, to employ the smallest amount of propylthiouracil that is necessary. For added safety, we have adopted the policy of using small doses of potassium iodide in conjunction with the propylthiouracil. It has been shown that thiouracil enters the blood of rat fetuses,¹³ and that in large doses this compound produces goiter and impairment of growth of the fetuses.¹³⁻¹⁵ Moreover, goiter has been observed at birth in a child,¹⁶ but the dosage of thiouracil was larger than is now known to be necessary. The mother receiving thiouracil probably should not nurse her child, since the concentration of the compound in milk is high.¹⁷

SUMMARY

Of 111 thyrotoxic patients who were treated with thiouracil and had a cessation of therapy, 51 are in remissions that have lasted for three to thirty-one months. Forty-four patients have been free of thyrotoxicosis for more than a year after cessation of therapy, and 33 have remained well for more than eighteen months. Of all the patients who remained well without treatment for more than a year, only 1 had a relapse. Following the cessation of treatment with thiouracil, most of the patients who had a relapse had it within a few months: 70 per cent had it within two months, and 88 per cent within five months.

Factors that tended to favor persistent remissions were as follows: female sex, small goiter and a mild degree of thyrotoxicosis. The age of the patient, the duration of the disease and the nodularity of the thyroid gland were not found to exert a significant influence, but these factors may prove important when larger series of cases are analyzed.

The good effects obtained with thiouracil encourage the frequent use of its less toxic derivative, 6-propylthiouracil, in the treatment of thyrotoxicosis. This therapy, radioactive iodine or a combination of the two appears to offer the most satisfactory method of treating the majority of patients with thyrotoxicosis, but further experiences may reveal complications from these types of treatment that are of greater magnitude than are anticipated at present. Therefore, patients treated by these newer methods must be followed carefully.

ACUTE BRUCELLOSIS AMONG LABORATORY WORKERS*

LIEUTENANT CALDERON HOWE, (MC) U.S.N.R., CAPTAIN EDWARD S. MILLER, MC, A.U.S.,

LIEUTENANT (JG) EMILY H. KELLY, H(W) U.S.N.R., CAPTAIN HENRY L. BOOKWALTER,

MC, A.U.S., AND MAJOR HAROLD V. ELLINGSON, MC, U.S.A.

UNDULANT fever occurs frequently among laboratory workers handling cultures of Brucella organisms.¹ This report is a summary of such infections in 17 persons engaged in investigative work with these organisms. The organization of the laboratories at Camp Detrick made it possible to gather serologic data before infection. These cases offered an unusual opportunity to observe the clinical course of this disease from the onset of illness and to submit several chemotherapeutic agents to clinical trial.

A Brucella vaccine was given to all members of the laboratory group, including the 17 who subsequently contracted brucellosis. Vaccination produced changes in the agglutination reaction and the opsonocytaphagic index, and may have altered the course of illness. This report is not concerned with an evaluation of the prophylactic efficacy of the vaccine.

The patients were all previously healthy young adults who gave no history or laboratory evidence of past Brucella infection. They had been under our direct observation or cognizance for three to fourteen months, the average period being six and a half months. The diagnosis in these patients was based on the clinical course of the disease, the development of high Brucella agglutinin titers and, in most cases, the isolation of the etiologic agent from the blood. Tables 1 and 2 present many of the pertinent data.

*From the Station Hospital, Camp Detrick, Frederick, Maryland.

CLINICAL ASPECTS

Incubation Period

The data are of limited help in determining the incubation period, since all the patients were in almost daily contact with the infecting organism for three to thirteen months before they became ill. The incubation period was known to have been at least four weeks in 1 case, since there had been no opportunity for exposure for that length of time immediately preceding the onset of the illness.

Symptoms

The interval between the appearance of the first prodromal symptoms and the time when illness was well established and incapacitating was less than twenty-four hours in 4 patients. The interval was less than seven days in all patients except one, whose symptoms increased slowly over a thirty-day period.

The clinical picture presented by nearly all patients on admission to the hospital was that of an acute and moderately severe febrile illness. The symptoms were such as are frequently associated with many other acute infectious diseases and were in no way pathognomonic. Chief among them was fatigue, which was experienced to a moderate or marked degree by all patients in the series. Aches and pains in the muscles or joints, or both, occurred in 15 patients, the pains, which were usually dull, intermittent, multiple and not clearly localized, often recurred far into the period of convalescence.

Headache was present during the acute phase of chills. Other symptoms included mild nonproductive cough, moderate nausea, occasional vomiting.

prominent symptom in a few. Approximately half the patients experienced one or several shaking and photophobia. Diarrhea was present in 4 patients, being moderately severe in two.

Signs

Physical examination in most cases disclosed no abnormalities other than fever and prostration. The fevers were characterized by great variability. The fevers were usually irregular and intermittent in type,

abnormalities other than fever and prostration. The temperature charts exhibited by these patients with temperatures highest in the late afternoon, and showing diurnal swings of 1 to 4°. Most patients

had peak temperatures of 102 to 104°F during the acute illness. Four patients showed definite periodic undulations of fever, with intervening periods of apyrexia. One patient (Case 11) experienced a four-day episode of sustained high temperature and great prostration, reminiscent of the malignant type of brucellosis. The total number of days of fever — that is, a temperature above 99°F orally — varied from thirteen to ninety-seven, and averaged thirty-

with diarrhea. In a few cases, joint pains were accompanied by joint tenderness, but there were no other objective signs of arthritis. Herpes febrilis appeared in 2 cases.

Clinical Course

The course of patients infected with *Brucella suis* was not discernibly different from that of patients

TABLE 2 Summary of Clinical and Laboratory Data in 8 Patients with Acute Brucellosis

five days. In general, the intensity of symptoms and the degree of prostration were directly proportional to the degree of fever. These descriptions are based on observations made when the patients were not receiving antipyretic drugs.

The spleen could be palpated in only 1 patient (Case 3), and then only after she had suffered pulmonary infarcts. Two patients exhibited moderate generalized abdominal tenderness coincidental

infected with *Br. melitensis*. Only one episode of acute illness occurred in 5 patients, two episodes in 9 and three episodes in 2, whereas 1 patient experienced five distinct attacks. In some cases the initial attack was the severest, and in others, subsequent attacks were more prostrating and prolonged. In patients who had an undulating type of fever, the peak of temperature and the intensity of symptoms tended to diminish with succeeding undulations.

Increased physical activity was often followed by relapses. Patients were therefore kept in bed during febrile periods and were permitted only gradual increases in activity during convalescence. The convalescent period was long because of a persistent state of lassitude and easy fatigability that lasted for months after all other evidence of illness had disappeared. The shortest illness was observed in Case 2, in which the patient had recovered, appar-

LABORATORY DATA

Blood Cultures

In taking blood cultures, two types of medium were used routinely. On each occasion, 15 cc of blood was withdrawn, of which half was added to 100 cc of nutrient broth and half to 100 cc of Bacto-Tryptose broth. All blood cultures were incubated under aerobic conditions at 37°C, and were

ently completely, four months after the onset. The longest illness was observed in Case 3, and after twelve months the patient continues to have occasional symptoms. Five of the other patients still complain of easy fatigability five to twelve months after the onset of disease. None of the patients exhibited signs of localized *Brucella* infection in any particular organ or system.

subcultured repeatedly on tryptose-agar plates. All cultures were held for fourteen days before being discarded. In the majority of cases the organisms grew equally well in both mediums. When specimens were taken during sulfadiazine therapy, 5 mg of para-aminobenzoic acid was added to each 100 cc of medium. When cultures were taken during streptomycin therapy 25 mg of cysteine hydro-

chloride was added to each 100 cc of medium to inhibit the action of this antibiotic

Br suis was isolated from the blood in 8 cases, and *Br melitensis* in 7. One or more positive blood cultures were obtained in most patients during the initial acute phase of illness, and usually again during subsequent febrile relapses. It is worth emphasizing the fact that blood cultures were occasionally positive during periods when symptoms were minimal and when temperatures were normal throughout the day.

Agglutination Tests

The macroscopic tube-agglutination technic used in the United States Army² was employed. The antigen was a standardized suspension of *Br abortus* prepared at the Army Veterinary School. Titers were expressed in terms of the highest final dilution of serum at which agglutination was visible with the aid of a concave magnifying mirror (Table 1). Prior to immunization no titer exceeded 1:25, and after immunization none exceeded 1:400. This serologic response to immunization usually fell after one or two months.

In all patients there was a sharp rise in agglutinins within three or four weeks of the onset of illness. Maximum titers of 1:1600 to 1:12,800 were reached in one or two months, after which the titers usually dropped slowly. After six months the agglutinin titers varied from 1:400 to 1:1600.

The height of the agglutinin titer was not proportional to the severity of illness, nor did it show consistent variations with remissions or exacerbations. It can be said that agglutinin determinations were useful for diagnosis but not for prognosis.

Opsonocytaphagic Index

This test* was performed essentially as outlined by Huddleson.³ The opsonocytaphagic index was usually altered by immunization so that the interpretation of subsequent determinations was difficult. Table 1 shows that the indexes increased in 9 patients after infection as compared with preinfection determinations, whereas in 8 patients they remained at the same level or actually fell. In this series the opsonocytaphagic index was therefore of questionable diagnostic value. As with the agglutination test, the index showed no predictable variation with alterations in clinical course and thus did not aid in prognosis.

Skin Tests

None of the 17 patients showed skin sensitivity to 0.1 cc of undiluted brucellergen administered intradermally prior to immunization. The test was repeated after immunization and in one patient was

positive. Skin tests were not performed after the onset of illness because of the danger of precipitating systemic reactions during the course of active infection. A phenomenon of great interest was observed in 8 patients after the onset of clinical illness: erythema and edema appeared spontaneously at the sites of the previous skin tests and vaccine injections, and in 1 case the inflammatory lesion progressed to actual necrosis. It must be emphasized that these delayed inflammatory phenomena developed in 6 patients from four to six months, and in 2 patients one and sixteen months, respectively, after the administration of the brucellergen or vaccine. The lesions appeared during the acute illness, faded during remissions, and reappeared with subsequent exacerbations.

Chest X-Ray Examination

Roentgenograms were taken routinely on admission and at intervals thereafter. They were consistently normal, except in Case 3, in which the patient, while receiving continuous intravenous streptomycin therapy, developed thrombophlebitis followed by bilateral pulmonary infarcts.

White-Cell Counts

The blood in all cases showed a leukopenia with a relative lymphocytosis. This finding frequently persisted beyond the stage of acute illness. There were no abnormal cell forms.

TREATMENT

A summary of the treatment in these cases is presented in Table 1. Eleven patients received sulfadiazine, 2 were given penicillin and sulfadiazine simultaneously, 3 received streptomycin, and 2 were given only symptomatic therapy. One patient (Case 5), who was given a course of sulfadiazine during a relapse following streptomycin therapy, is included in both groups. The table shows the duration of fever before and after initiation of chemotherapy for each patient. These figures cover the span of a single acute episode and afford a rough index of the clinical response to the given chemotherapeutic agent.

Sulfadiazine Therapy

Unpublished experimental data from the technical laboratory at this station indicated that thirty days of sulfadiazine therapy in guinea pigs infected with *Br suis* resulted in a definite modification of the disease. Because of these encouraging results, 11 patients were treated with sulfadiazine for periods of twenty to thirty days. Blood levels of free sulfadiazine were maintained well in excess of concentrations required to inhibit the growth of *Br suis* in vitro. There was no clear-cut, abrupt amelioration of symptoms, the temperatures dropped to normal in one to eleven days after the beginning of treatment. In all but 1 of these 11 patients, after the

*The cells were categorized according to the degree of phagocytosis, as "negative," "slight," "moderate" or "marked" according to Huddleson's criteria. The category containing the greatest number of cells was then taken as the final reading for the slide. When two categories contained an equal number of cells, the two remaining categories were considered in determining the final reading.

temperature had returned to normal, there were no marked elevations during the remainder of the therapeutic period. Ten patients had positive blood cultures prior to treatment. Blood cultures were taken during treatment in 6 cases and were positive in 4, on the second to sixth days of treatment. The evaluation of therapeutic efficacy of a drug is admittedly difficult in a disease whose course is as variable as that of brucellosis. Nevertheless, there seemed little clinical evidence that sulfadiazine therapy had benefited these patients. There was in fact ample evidence that none of them had been cured, for all 11 patients in this group suffered one or more relapses after cessation of therapy. During these relapses, blood cultures were positive in 7 cases, negative in 3 and were not taken in one.

Strains of *Brucella* isolated before, during and after therapy were tested in vitro for sensitivity to sulfadiazine. There was no demonstrable decrease in sensitivity as a result of therapy.

Simultaneous Administration of Sulfadiazine and Penicillin

The 2 patients in this group received treatment for twelve and nine days respectively. Penicillin was given intramuscularly, and sulfadiazine by mouth. In neither case was there a definite clinical response to therapy. One patient (Case 1) had a short relapse with positive blood cultures subsequent to treatment, since that time she has been well. The other (Case 2) has apparently recovered completely.

Streptomycin Therapy

Streptomycin hydrochloride* was submitted to clinical trial in 3 cases. Studies of absorption and excretion of streptomycin in these patients are reported elsewhere.⁴ The drug was administered intramuscularly or intravenously. There was no apparent clinical response in these patients. All 3 had positive blood cultures prior to treatment, and 2 (Cases 3 and 5) had negative cultures during treatment. No blood cultures were taken during treatment in the third case. In Cases 3 and 5 the

patients had one or more relapses, one with positive blood cultures and the other without. The subsequent course in Case 4 has not been ascertained, since we were unable to observe the patient following recovery from the initial episode.

Symptomatic Therapy

As stated above, the symptoms in most patients were directly proportional to the degree of fever. It was found that acetylsalicylic acid in doses of 0.3 to 0.6 gm administered regularly every four hours resulted in a sharp drop in fever and a coincidental decrease in malaise, muscular aching and headache.

SUMMARY AND CONCLUSIONS

Clinical and laboratory data from 17 cases of brucellosis are presented. The patients were laboratory workers engaged in investigative work with strains of *Brucella suis* and *Br. melitensis*.

Eleven patients were treated with sulfadiazine for periods of twenty to thirty days. There was no evidence that this therapy altered the natural course of the disease. Of the remaining patients, 3 were treated with streptomycin, and 2 with penicillin and sulfadiazine simultaneously. From this limited clinical experience there was no indication that these drugs were of therapeutic benefit.

Addendum. The status of 14 out of these 17 patients was ascertained as of January 1, 1947, approximately two years after the occurrence of the first case. The status of 3 patients (Cases 2, 10 and 17) is unknown. One patient (Case 3) has had more than ten febrile episodes since the onset of her illness, and continues to experience severe symptoms. Three patients (Cases 4, 13 and 16), who are back at normal activity and no longer exhibit fever, report mild occasional symptoms. The remaining 10 patients are well, following illnesses lasting from one to twelve months (average, slightly less than six months).

MEDICAL PROGRESS

STREPTOMYCIN (Concluded)*

II Clinical Uses

TOM F. PAINE, M.D.,† Roderick Murray, M.D.,‡ AND Maxwell Finland, M.D.§

BOSTON

THE present knowledge of the clinical usefulness of streptomycin is largely the result of a co-ordinated effort by the streptomycin producers with the medical departments of several governmental agencies, including the Army, Navy, Public Health Service and Veterans Administration, as well as many physicians throughout the country. Under the guidance of the Committee on Chemotherapeutics and Other Agents of the National Research Council and with funds contributed by several pharmaceutical and chemical companies, limited amounts of streptomycin were apportioned to civilian physicians for the purpose of investigating its effectiveness in a wide variety of conditions. Much valuable information was thus accumulated in a short time, although there is still need for further investigation.²⁰² The practical aspects of streptomycin administration, the results of treatment of various infections and the toxic effects observed are considered below.

ADMINISTRATION AND DOSAGE

Streptomycin, as either the hydrochloride or the sulfate, is usually supplied as a dry, sterile powder in airtight rubber-capped vials each containing the equivalent of 1.0 gm (1,000,000 units) of the streptomycin base. Streptomycin and its salts are reasonably stable, but storage at a temperature not above 15°C is recommended. Solutions are less stable than the dry powder and should be kept in a refrigerator.⁴⁰

Streptomycin may be administered parenterally, orally or locally. The intramuscular route is the one generally used for parenteral administration. The subcutaneous route may be used, but it is likelier to cause pain and local irritation. Intravenous injections are used chiefly to attain high concentrations rapidly or to avoid local irritation, immediate systemic reactions, however, are more frequent with this route.²⁰² Various investigators have given the drug orally.^{45, 183, 202, 203} Topically,

streptomycin has been applied intrathecally,^{72, 80, 81-119, 202, 204, 205} intracisternally,²⁰⁶ into the lateral cerebral ventricles, through the anterior fontanelle, in infants,⁸¹ intrapleurally,^{206, 207} intraperitoneally,²⁰² cystoscopically into the urinary bladder and kidney pelvis,³¹ by inhalation,^{82, 202, 208} intratracheally,²⁰⁹ by gauze soaks to cutaneous areas⁷⁴ and by drops on the conjunctiva,^{210, 211} into the nose²¹² and into the external auditory canal.⁸²

Parenteral Administration

The object of parenteral streptomycin is to maintain an inhibitory concentration in the blood stream and at the sites of infection. The concentration of streptomycin required to inhibit different bacteria varies considerably, and clinical results do not always correspond to the in vitro sensitivity of the bacteria.^{57, 62, 84, 146, 203} On general principles, it seems wise to administer large doses of streptomycin and thus to maintain high blood and local concentrations.^{202, 213-216} In adults the intramuscular administration of 1.0 gm of streptomycin at six-hour intervals is ordinarily adequate for most infections. This dose is usually well tolerated and provides a good margin of therapeutic safety, but smaller doses have generally been used.²⁰² Somewhat larger doses—up to 8 gm a day—may be given to adults if indicated.[¶] Infants and children require smaller doses, 30 to 75 mg per pound of body weight, or a total of 0.25 to 2.0 gm daily should be adequate.^{80, 81, 204}

Intermittent intramuscular injection is the parenteral method of choice. The gluteal regions, the lateral aspects of the thighs and sometimes the triceps muscle may be used in rotation. Each gram of streptomycin is dissolved in 4 or 5 cc of sterile, pyrogen-free distilled water or physiologic saline solution. This volume can be administered with only slight discomfort to the patient, but, if desired, 1 cc of 1 per cent procaine hydrochloride may be added to each 4 cc of streptomycin solution. A more dilute solution—0.1 gm per cubic centimeter—may be used for intramuscular injections of 0.5 gm or less. The solution should be clear and free of undissolved particles.²⁰² For continuous intra-

¶Associate professor of medicine, Harvard Medical School, associate physician, Thorndike Memorial Laboratory and chief, Fourth Medical Service, Boston City Hospital.

¶It has been stated that infections will not be influenced regardless of the amount of streptomycin given, if the infecting organism grows in 16 microgm per cubic centimeter and furthermore that no additional benefit may be expected regardless of the type or severity of the infection from doses greater than 3.0 gm a day.⁴¹ This is at variance with our experience.

venous administration 1 or 2 gm may be dissolved in a liter of physiologic saline solution and given at the rate of about twenty-five drops a minute. For single or intermittent intravenous injections, 1.0 gm of streptomycin is dissolved in 20 cc or more of physiologic saline solution and injected slowly.⁶⁵

Oral Administration

Streptomycin is absorbed only to a slight extent after its ingestion, and little appears in the bowel contents during parenteral administration. The ingestion of 2 to 5 gm daily in orange juice or other liquids is well tolerated and produces a marked reduction in the number of most of the susceptible organisms in the feces.^{64, 202} The method has been used in preparing patients for operations on the bowel.^{65, 217}

Local Administration

Intrathecal injection. Since adequate diffusion of streptomycin from the blood into the cerebrospinal fluid cannot be relied on,^{69-73, 218, 219} systemic therapy should be supplemented by local administration in the treatment of meningitis. Doses of 50 to 200 mg dissolved in 5 to 10 cc of physiologic saline solution may be given intrathecally every twelve to forty-eight hours.^{202, 204, 205} Injections of more than 50 mg, however, may produce signs of meningeal irritation.^{71, 119, 206} As much as 25 mg a day has been given intraspinally, intraventricularly or directly into a meningocele sac in infants who were about two weeks old.⁶¹ Streptomycin has been injected safely into infected lateral cerebral ventricles⁶¹ and into the basal cistern.²²⁰

Inhalation. Streptomycin may be administered for bronchopulmonary disease either as an aerosol²⁰³ or by intratracheal instillation.²⁰⁹ Doses of 50 to 100 mg in 1 cc of physiologic saline solution may be nebulized at intervals of two to six hours.²⁰² More concentrated solutions are unsatisfactory for aerosols and are wasteful because their viscosity causes frothing and because the nebulizer tends to clog.

Other routes. Streptomycin has been applied directly to the urinary bladder and kidney pelvis through a cystoscope or an indwelling catheter,²¹ but such an approach offers no advantage over parenteral therapy since the drug is usually excreted in a high concentration in the urine. The antibiotic has been injected intrapleurally in the treatment of empyema.^{202, 205} The optimum dosage by this route is not known, but 50 to 500 mg in 25 to 100 cc of physiologic saline solution can probably be introduced safely into the infected pleural cavity. As much as 1 gm has been put into the pentoneal cavity at the time of operation.⁷⁴ Solutions containing 10 mg per cubic centimeter have been applied to the conjunctiva (two drops every four hours) without harmful effects.^{210, 211} Streptomycin in concentrations up to 25 mg per

cubic centimeter has been instilled into the auditory canals of patients with suppurative otitis without ill effects.²²¹ It has been used as nose drops in a concentration of 10 mg per cubic centimeter, five drops being administered into each nostril every three hours.²¹² It has been applied locally to wounds in concentrations of 0.2 to 0.5 mg (200-500 units) per cubic centimeter.⁷⁴

URINARY-TRACT INFECTIONS

Streptomycin has been used extensively in the treatment of urinary-tract infections.^{21, 50, 74, 84-86, 194, 202, 203, 212-214, 222-225} The report of the National Research Council²⁰² includes 409 cases with an overall recovery rate of 42 per cent based mostly on short periods of observation. Similar results were obtained in 264 cases treated in Army hospitals.²²⁵ Almost all civilian patients had previously been treated ineffectively with sulfonamides and penicillin. A considerable number improved during streptomycin treatment but then relapsed, generally during the first week after cessation of therapy.

Several points have been emphasized. Many patients show definite clinical improvement without bacteriologic remission. Many who improve are cured bacteriologically but do not recover clinically because the underlying anatomic irregularities are not corrected. Infections due to a single organism respond oftener than mixed infections do. Rapid development of resistance during treatment is frequent and accounts for many of the failures. A minimal follow-up period of a week is essential before any patient with a urinary-tract infection can be considered recovered. All cases should be carefully studied to determine the nature of the infection, the sensitivity of the organisms, the reaction of the urine and the presence of underlying anatomic lesions.^{202, 213}

In the treatment of urinary-tract infections in patients with neurogenic bladders following spinal injuries streptomycin has proved useful only for controlling the severe infections and associated septicemias.^{21, 194, 225} In such cases only 28 per cent of patients improved, as compared with 54 per cent among those without spinal-cord injuries.²²⁵ Streptomycin-resistant strains often developed in these cases, and even when this did not happen, cessation of therapy was promptly followed by the appearance of new infections. There was no advantage in the use of streptomycin locally.²¹

Alkalinization of the urine may be an important adjunct to streptomycin therapy of urinary-tract infections because of the increased activity of streptomycin in an alkaline medium.⁶⁰ In 21 cases studied at the Boston City Hospital the first 7 patients were treated without alkalis, and failures in 6 cases were associated with the development of highly resistant strains of bacteria during treatment.⁸⁵ On similar doses of streptomycin, usually 4 to 6 gm daily, but with alkalinization of the urine

¶It has been stated that infections will not be influenced regardless of the amount of streptomycin given if the infecting organism grows in 16 microgm per cubic centimeter and furthermore that no additional benefit may be expected, regardless of the type or severity of the infection from doses greater than 30 gm a day.¹¹ This is at variance with our experience.

amide or penicillin treatment. Infections due to *H influenzae* may be frequent and serious in infants and children. Several streptomycin-treated cases due to these organisms have been reported^{74-76, 202-209, 215, 236-238}. A few cases of acute pneumonitis, apparently due to *H influenzae*, responded favorably to streptomycin after failing to improve on sulfonamides and penicillin^{82, 200, 215}. The institution of streptomycin therapy in these patients was followed by prompt clinical improvement and disappearance of *H influenzae* from the sputum.

Pneumonia due to Friedländer bacillus has a high mortality rate²⁹ that has not been strikingly influenced by sulfonamides or penicillin. The response to streptomycin in such cases has not been uniformly favorable,^{74, 82, 202-225, 240} in spite of the fact that the causative organism, *K pneumoniae*, is usually quite sensitive to the drug. The results are readily understandable when one considers the pathology of this disease, which is marked by the early development of multiple pulmonary cavities filled with viscid exudate. Four cases of pneumonia due to Friedländer bacillus have been reported in which streptomycin therapy begun after several days of ineffective sulfonamide or penicillin therapy, or both, resulted in prompt improvement^{202-215, 241}. One case is reported in which a resistant strain of *K pneumoniae* developed in the sputum after two days of streptomycin therapy, the patient nevertheless improved promptly and eventually recovered⁸². In view of the high mortality in pneumonia due to Friedländer bacillus, the prompt institution of large doses of streptomycin — preferably 10 gm every four hours in adults — seems indicated.

In a case of severe pharyngitis apparently due to *P aeruginosa* in a child with leukemia, the organisms quickly disappeared from the throat following institution of streptomycin therapy²⁰².

Chronic Infections

Chronic bronchiectasis is a distressing and debilitating disease. Treatment of such cases with penicillin aerosol in conjunction with postural drainage has proved to be of much help in reducing the amount of sputum, decreasing the incidence and severity of the episodes of superimposed pneumonitis and in preparing the patients for operations²⁴¹. Penicillin, however, eliminates only the penicillin-sensitive organisms, and in some patients the infection persists, owing to the presence of the penicillin-insensitive organisms, mostly gram-negative bacilli. The response of such cases to streptomycin has been encouraging^{82, 208, 209, 218}. The volume of sputum diminishes, and gram-negative bacilli disappear promptly following inhalations of streptomycin aerosol²⁰⁸. The total daily dose of nebulized streptomycin used in some of these cases was 0.5 gm. in 20 cc of saline solution daily²⁰⁸. Similar cases have been treated by daily intratracheal instillations of 5 cc of streptomycin solution contain-

ing 10 mg per cubic centimeter, with similar favorable results²⁰⁹.

The ease of administration of antibiotics by aerosol offers a simple but often effective means of treating patients with chronic bronchiectasis and chronic bronchitis. Whether or not concomitant parenteral therapy in these patients is advantageous has not been determined, and the problem of development of resistance by the organisms under aerosol treatment must be investigated further⁸². The rational aerosol treatment of chronic bronchiectasis may well involve the combined use of penicillin and streptomycin²⁰⁸. Such treatment is probably only palliative but may offer considerable relief from the distressing symptoms, lessen the frequency of complications and possibly arrest the progress of the disease.

Empyema

Several cases of empyema thoracis have been treated with variable results. Details in these cases are lacking^{202, 225}.

Nasal and Sinus Infections

A case of chronic sinusitis due to *K pneumoniae*²¹⁷ was treated with 100 mg of streptomycin aerosol five times daily given by the method of Barach and his associates²⁴². The patient had undergone two episodes of pneumonia due to Friedländer bacillus during the previous two years. The Friedländer bacilli were promptly eliminated from the nose and sputum. Four patients with ozena possibly due to *K pneumoniae* were treated by parenteral streptomycin, with symptomatic improvement²⁴³.

BACTERIAL ENDOCARDITIS

There are few reports on the use of streptomycin in bacterial endocarditis. Although endocarditis due to gram-negative bacilli is infrequent, the early use of streptomycin in such cases seems indicated. The only reported recovery occurred in a case of subacute bacterial endocarditis due to an unidentified gram-negative bacillus²⁴⁴. Streptomycin therapy was started in that case after several days of treatment with penicillin and sulfadiazine. Although cultures had already become negative, it was thought that the streptomycin helped effect the cure.

The usefulness of streptomycin in endocarditis, however, may not be limited to infections with gram-negative bacilli. Indeed, the drug may be superior to penicillin in certain infections, such as those due to enterococci and nonhemolytic or alpha-hemolytic streptococci, that are resistant to the concentrations of penicillin maintained in the blood but sensitive to those attainable with streptomycin. Three cases of subacute bacterial endocarditis caused by such organisms were reported¹³². Two of them were due to nonhemolytic streptococci that were inhibited by 1 unit of streptomycin but required 6 units of penicillin in one case and 4 units in the other. Treatment with streptomycin was

during the streptomycin treatment in the remaining 14 cases, 8 patients were cured and 6 were temporarily improved. Only 1 of the latter developed a resistant organism during treatment, and the other 5 had recurrences of infection following the cessation of streptomycin, possibly because of uncorrected anatomic defects in the urinary tract. These patients were followed for two to four months. Alkalinization of the urine was usually accomplished by the oral administration of 1 gm each of sodium bicarbonate and potassium citrate every four hours, but larger doses were sometimes required. The urine was checked frequently during therapy to ensure that an alkalinity actually existed.

Albright²²⁹ has had good results with streptomycin in cases of urinary infections associated with renal stones. Alkalinization with sodium citrate was used routinely in his cases. Kane and Foley²³⁰ treated 40 cases due to gram-negative bacilli at the Massachusetts General Hospital and followed them for four to eight months. Cures were obtained in 30 cases, 4 patients were improved, and 6 cases were failures. Alkalies were given to all, and a resistant strain developed in only 1 case.

INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

Streptomycin has proved of great value in the treatment of infections of the central nervous system due to gram-negative bacilli. It has been used most extensively in meningitis caused by *Haemophilus influenzae*.

Meningitis due to H. Influenzae

The report of the National Research Council²⁰² includes 100 cases. 66 of the patients were cured clinically and bacteriologically while under treatment, 13 improved under treatment and finally recovered, 1 improved but relapsed, 3 showed no effect, and 17 died. Eighteen of the 66 patients who recovered received streptomycin alone, the others received, in addition, various combinations of sulfonamides, penicillin and antiserum. The average daily dose of streptomycin was 0.5 gm intramuscularly and 60 mg intrathecally.

Several authors^{57, 70, 75, 80, 81, 119, 203, 204, 206, 218, 219, 225, 227, 231, 232} have reported cases of *H. influenzae* meningitis that were treated with streptomycin, and many of these cases were probably included among the 100 mentioned above. Analysis of the individual reports, however, yields valuable information. When streptomycin therapy alone was instituted early in the course of the disease and in adequate amounts, the results were almost uniformly favorable.^{80, 203} When the treatment was begun late in the disease, the results were quite irregular. The findings indicate that streptomycin alone, in adequate doses intramuscularly and intrathecally, is effective if the treatment is begun early in the course of the disease, sulfadiazine and antiserum should also be used when treatment is started late. The

streptomycin should be given for at least seven days.²¹³

The development of streptomycin-resistant strains of *H. influenzae* has been noted in 4 cases during the course of treatment.^{80, 119, 203} This untoward phenomenon should be looked for at the first sign of a recrudescence of clinical symptoms and signs or when *H. influenzae* reappears in the cerebrospinal fluid. Sulfadiazine and specific rabbit antiserum should then be added to the therapeutic regime. The occurrence of secondary infections during streptomycin treatment must be watched for constantly and treated vigorously as soon as recognized. Complicating staphylococcal infections were reported in 3 children under streptomycin treatment for *H. influenzae* meningitis.²⁰⁴ One of them died of staphylococcal pneumonia, despite added penicillin therapy, the second had an acute otitis media, and the third had a meningitis due to a staphylococcus, and both responded favorably to penicillin.

Meningitis Due to Miscellaneous Gram-Negative Bacilli

There are reports of streptomycin treatment in cases of meningitis due to the following gram-negative bacilli: *Aerobacter aerogenes*,²²⁵ *Alcaligenes faecalis*,²⁰² *Escherichia coli*,^{202, 218, 220, 225, 226} *Proteus morganii*,^{81, 202} *Pr. vulgaris*,²²⁵ *Klebsiella pneumoniae*,^{202, 224} *Salmonella choleraesuis*,^{202, 225} *Pseudomonas aeruginosa*,^{81, 206, 225} and an achromobacterium.²⁰⁶ The over-all mortality rate in these cases was high, but inspection of the data shows that when streptomycin therapy was instituted early in the course of the disease and given intrathecally as well as parenterally in adequate doses, the results were favorable. Infections of the central nervous system by gram-negative bacilli respond poorly to sulfonamides and little if at all to penicillin. The early and proper use of streptomycin in such cases may therefore be life saving.

Brain Abscess

Of 4 cases treated in Army hospitals, 3 patients improved, but only when parenteral streptomycin therapy was supplemented by drainage of the abscess and local instillation of streptomycin. Both gram-negative bacilli and gram-positive cocci were cultured in these cases.²²⁵ Improvement was noted in an additional case.²⁰²

INFECTIONS OF THE RESPIRATORY TRACT

Acute Infections

H. influenzae and *K. pneumoniae* are the only gram-negative bacilli—except in cases of tularemia, plague and glanders—that are important causes of primary acute pulmonary infections. Such infections are infrequent in adults, are usually superimposed on a chronic bronchiectasis or chronic bronchitis and generally respond poorly to sulfon-

amide or penicillin treatment. Infections due to *H influenzae* may be frequent and serious in infants and children. Several streptomycin-treated cases due to these organisms have been reported^{74-76, 202, 203, 213, 216-218}. A few cases of acute pneumonitis, apparently due to *H influenzae*, responded favorably to streptomycin after failing to improve on sulfonamides and penicillin.^{82, 209, 218} The institution of streptomycin therapy in these patients was followed by prompt clinical improvement and disappearance of *H influenzae* from the sputum.

Pneumonia due to Friedländer bacillus has a high mortality rate²¹⁹ that has not been strikingly influenced by sulfonamides or penicillin. The response to streptomycin in such cases has not been uniformly favorable,^{74, 82, 202, 218, 240} in spite of the fact that the causative organism, *K pneumoniae*, is usually quite sensitive to the drug. The results are readily understandable when one considers the pathology of this disease, which is marked by the early development of multiple pulmonary cavities filled with viscid exudate. Four cases of pneumonia due to Friedländer bacillus have been reported in which streptomycin therapy begun after several days of ineffective sulfonamide or penicillin therapy, or both, resulted in prompt improvement.^{203-205, 211, 217} One case is reported in which a resistant strain of *K pneumoniae* developed in the sputum after two days of streptomycin therapy, the patient nevertheless improved promptly and eventually recovered.⁸² In view of the high mortality in pneumonia due to Friedländer bacillus, the prompt institution of large doses of streptomycin — preferably 10 gm every four hours in adults — seems indicated.

In a case of severe pharyngitis apparently due to *Ps aeruginosa* in a child with leukemia, the organisms quickly disappeared from the throat following institution of streptomycin therapy.²⁰²

Chronic Infections

Chronic bronchiectasis is a distressing and debilitating disease. Treatment of such cases with penicillin aerosol in conjunction with postural drainage has proved to be of much help in reducing the amount of sputum, decreasing the incidence and severity of the episodes of superimposed pneumonitis and in preparing the patients for operations.²⁴¹ Penicillin, however, eliminates only the penicillin-sensitive organisms, and in some patients the infection persists, owing to the presence of the penicillin-insensitive organisms, mostly gram-negative bacilli. The response of such cases to streptomycin has been encouraging.^{82, 208, 209, 218} The volume of sputum diminishes, and gram-negative bacilli disappear promptly following inhalations of streptomycin aerosol.²⁰⁸ The total daily dose of nebulized streptomycin used in some of these cases was 0.5 gm. in 20 cc of saline solution daily.²⁰⁸ Similar cases have been treated by daily intratracheal instillations of 5 cc of streptomycin solution contain-

ing 10 mg per cubic centimeter, with similar favorable results.²⁰⁹

The ease of administration of antibiotics by aerosol offers a simple but often effective means of treating patients with chronic bronchiectasis and chronic bronchitis. Whether or not concomitant parenteral therapy in these patients is advantageous has not been determined, and the problem of development of resistance by the organisms under aerosol treatment must be investigated further.⁸² The rational aerosol treatment of chronic bronchiectasis may well involve the combined use of penicillin and streptomycin.²⁰⁸ Such treatment is probably only palliative but may offer considerable relief from the distressing symptoms, lessen the frequency of complications and possibly arrest the progress of the disease.

Empyema

Several cases of empyema thoracis have been treated with variable results. Details in these cases are lacking.^{202, 216}

Nasal and Sinus Infections

A case of chronic sinusitis due to *K pneumoniae*²¹⁷ was treated with 100 mg of streptomycin aerosol five times daily given by the method of Barach and his associates.²⁴² The patient had undergone two episodes of pneumonia due to Friedländer bacillus during the previous two years. The Friedländer bacilli were promptly eliminated from the nose and sputum. Four patients with ozena possibly due to *K pneumoniae* were treated by parenteral streptomycin, with symptomatic improvement.²⁴³

BACTERIAL ENDOCARDITIS

There are few reports on the use of streptomycin in bacterial endocarditis. Although endocarditis due to gram-negative bacilli is infrequent, the early use of streptomycin in such cases seems indicated. The only reported recovery occurred in a case of subacute bacterial endocarditis due to an unidentified gram-negative bacillus.²⁴⁴ Streptomycin therapy was started in that case after several days of treatment with penicillin and sulfadiazine. Although cultures had already become negative, it was thought that the streptomycin helped effect the cure.

The usefulness of streptomycin in endocarditis, however, may not be limited to infections with gram-negative bacilli. Indeed, the drug may be superior to penicillin in certain infections, such as those due to enterococci and nonhemolytic or alpha-hemolytic streptococci, that are resistant to the concentrations of penicillin maintained in the blood but sensitive to those attainable with streptomycin. Three cases of subacute bacterial endocarditis caused by such organisms were reported.¹²² Two of them were due to nonhemolytic streptococci that were inhibited by 1 unit of streptomycin but required 6 units of penicillin in one case and 4 units in the other. Treatment with streptomycin was

successful in the first case after five weeks of penicillin had proved ineffective. The second case was also treated with streptomycin after an unsuccessful course of penicillin. Blood cultures in this case were negative during streptomycin therapy, and the patient eventually recovered despite two positive blood cultures obtained after the streptomycin had been stopped. In the third case the organism was a strain of *Streptococcus viridans* that was inhibited by 0.8 units of penicillin and 0.1 units of streptomycin per cubic centimeter. Penicillin had produced no effect in this case. The patient died after five days of streptomycin treatment, but at autopsy no bacteria were found in the vegetations on the heart valves. In these 3 patients the dosage of streptomycin was small—only 0.5 gm a day. A fourth case, due to *Str. faecalis*, was treated unsuccessfully.^{245, 246}

In cases of subacute bacterial endocarditis due to gram-positive cocci that do not seem to respond to penicillin, the sensitivity of the organism to both penicillin and streptomycin should be determined if possible, and streptomycin treatment instituted if the organism is found to be insensitive to penicillin but sensitive to streptomycin. The dose in such cases should be large, preferably about 1.0 gm intramuscularly every four hours for adults.

ENTERIC INFECTIONS

Typhoid Fever

Streptomycin has not been particularly effective in the treatment of typhoid fever or of typhoid carriers. Fifty-one cases of typhoid fever were included in the report of the Committee on Chemotherapeutics and Other Agents.²⁰² The majority of these patients received 4.0 gm of streptomycin daily for seven or eight days without a favorable effect on the course of the disease. Combined oral and intramuscular therapy was used in 15 cases, with results that were no better than those in the cases treated by intramuscular injections alone. Others^{70, 84, 203-213, 218, 225, 240, 247, 248} have reported similar results. Oral and intramuscular streptomycin was ineffective in clearing up typhoid carriers.^{183, 248}

A case in an eighteen-year-old girl²⁴⁹ is worth citing. Treatment was begun on the twenty-seventh day of illness with 1.0 gm intramuscularly every four hours. This was increased to 1.5 gm every four hours after six days and then to 2.0 gm every four hours after another five days, and the latter dosage was continued until the patient died on the fortieth day. During the last five days of life, 3.0 gm of streptomycin was also given orally each day. Blood cultures eventually became negative, but stool cultures remained positive for *Escherichia typhosa* during this treatment. *Esch. coli*, however, disappeared from the stool cultures during this period. Strains of *E. typhosa* obtained from the stool and blood after eight days of therapy were

sensitive to 16 units. At autopsy, typhoid bacilli were grown from the blood, intestinal ulcers, urine and bile. The patient died despite intensive therapy, although the infection was due to an organism that was moderately sensitive in vitro.

Salmonella Infections

Streptomycin therapy of *Salmonella* infections has also been generally unsuccessful,^{70, 145, 202, 243, 250} although some cases may have been favorably influenced.^{202, 250} In 26 collected cases 10 patients recovered during treatment, 2 improved during treatment and later recovered, 6 showed no improvement and 8 died.²⁰² The treatment of enteritis due to *S. typhimurium* in 5 newborn infants has been reported.¹⁴⁵ Streptomycin was given orally to 4 and both orally and intramuscularly to 1 patient. There was little noticeable effect on the clinical course. The normal fecal flora and the pathogens were suppressed by oral doses of 25 to 100 mg every three hours for four days. The organisms reappeared promptly after the end of treatment. No increase occurred in the resistance of the organisms. Further trials of streptomycin with early and prolonged use of large parenteral and oral doses may be indicated in these infections.

Shigella Infections

In a case of bacillary dysentery due to *Shigella sonnei* streptomycin was given by mouth in doses of 1.0 gm five times daily for four days. The diarrhea and fever subsided in twelve hours, and the causative organisms disappeared promptly from the stools.²⁰³ This seemed to be a dramatic response to oral streptomycin alone. Two additional patients with bacillary dysentery due to *Shigella* responded promptly to streptomycin treatment, and stool cultures became negative.²⁰² Prolonged sulfonamide therapy had previously been ineffective in these cases. A prompt response was reported in 5 other cases.²²⁵

Cholera

In 8 Chinese patients suffering from cholera who were treated with streptomycin in doses of 4 gm daily by mouth supplemented by an occasional intravenous dose, there was little indication that the streptomycin offered any clinical advantages over the use of hydration or sulfonamides, or both.¹⁴⁴ The number of cholera organisms in the stools was apparently reduced promptly and markedly following oral streptomycin, although some were still present by culture and their resistance to streptomycin had increased from 5 to 500 units.

BILIARY-TRACT DISEASE

There are reports of 5 cases of cholangitis, with or without cholecystitis, and 2 cases of liver abscess treated with streptomycin, in all of which the patients improved.²⁰² A patient with cholecystitis

improved with streptomycin, but only after cholecystectomy.²⁵ In a case of liver abscess due to an anaerobic hemolytic streptococcus the patient improved, also after surgical drainage.²⁵ Observations on the excretion of streptomycin in such cases indicate that, for the drug to be effective in cholecystitis or cholangitis, it is necessary that liver function be unimpaired and biliary drainage be free.²⁵

PERITONITIS

The reported results of streptomycin therapy in peritonitis are quite variable, as might be expected. Controlled observations in animals and some highly favorable clinical results suggest that it may be of value in cases of peritonitis due to susceptible organisms. In dogs, the mortality from experimental peritonitis was reduced from 70 per cent in controls to 40 per cent in subjects treated with streptomycin.⁸³ In another study, however, better results were obtained in dogs with the use of penicillin and sulfonamides than with streptomycin.⁸⁴ In a collected series of 53 human cases of peritonitis of varied etiology, there were 39 recoveries, 12 deaths and 2 cases in which there was no effect. Most of these patients received 1 or 2 gm daily for eight days, and more than half of those who recovered also received other forms of chemotherapy. In this series there were only 3 deaths in 21 cases complicating appendicitis.²⁰²

No spectacular effects were reported from streptomycin on the course of peritonitis in 12 patients, most of whom also received penicillin in what may now be considered small doses. There was only 1 death among 7 cases in which the peritonitis was secondary to appendicitis, and 1 death in 5 cases that were secondary to perforated peptic ulcers. Coliform organisms were most frequent in cultures of the former, and alpha-hemolytic streptococci predominated in the latter.⁷⁴ In Army hospitals, about 80 per cent of the streptomycin-treated cases of peritonitis recovered, but the infection had already been localized in half the cases when the streptomycin therapy was started.²²⁵

A prompt response to streptomycin was noted in 2 isolated cases, one due to a colon bacillus²²¹ and the other to *Ps. aeruginosa*.²⁰³ A third case of peritonitis associated with a ruptured appendix was treated successfully with streptomycin in conjunction with appendectomy and surgical drainage.²²⁴ Good results were also noted from streptomycin given prophylactically to 2 patients in whom the peritoneum was accidentally contaminated during an operation.⁷⁴

Streptomycin may be useful as a prophylactic agent in the preparation of patients for large-bowel surgery because of the marked reduction in the intestinal flora that follows its oral administration. This reduction is usually greater than that following

succinylsulfathiazole,⁸⁶ but occasionally it may not occur.²¹⁷

The optimum treatment of peritonitis may involve the simultaneous use of large doses of both penicillin²³² and streptomycin, with the realization that in the presence of pocketed collections of pus the response to therapy may be slow but that complications may be avoided and the eventual duration of the disease shortened.

INFECTIONS OF THE EYE

Good results were reported in 9 patients with corneal ulcers treated by streptomycin solutions placed on the conjunctiva.²¹¹ There were no bacteriologic reports in these cases, but gram-negative bacilli may cause such infections.²³⁴ One patient²¹⁰ with a severe corneal ulcer due to *Esch. coli* responded quickly to streptomycin after treatment with penicillin intramuscularly and locally and with sulfadiazine by mouth had failed.

INFECTIONS OF THE EAR

There are few reports on the streptomycin treatment of infections of the ear. One report includes 8 cases of otitis media, with improvement in 7 and no effect in 1.²⁰² A child with otitis media and mastoiditis due to *Ps. aeruginosa* failed to respond to streptomycin.²⁰³

Streptomycin has been used locally in 27 cases of suppurative ear infections that were mainly due to chronic otitis media.²²¹ Streptomycin preparations containing 1 to 20 mg per cubic centimeter of physiologic saline solution were instilled four times daily for one to seven weeks. Drainage stopped during treatment and did not recur during follow-up periods of one to four months in about half the cases. In the others the discharge persisted or recurred after temporary improvement. Changes in the bacterial flora were frequent, and streptomycin-resistant strains developed in many of the cases during treatment.

Otitis externa was treated with wicks saturated with streptomycin solutions of 2.5 to 5 mg per cubic centimeter in 6 cases, 5 patients improved and 1 with insensitive organisms was unimproved.²²⁵ In 3 cases of mastoiditis, 2 patients were improved and 1 unaffected by streptomycin, but all 3 required surgery.²²⁵

INFECTIONS OF SKIN, WOUNDS AND BONES

Streptomycin solutions, in the form of 2 to 5 mg per cubic centimeter on wet dressings, were applied directly to sloughing or granulating wounds of 4 patients with burns or avulsions.⁷⁴ All improved, granulations became red and healthy, and grafts took well. The bacterial flora, however, did not change, except that the resistance of some of the organisms to streptomycin increased markedly. In 19 patients with infections of the skin, 11 improved and 8 showed no effect from streptomycin given

intramuscularly or, in some cases, topically.²⁰² Six patients with operative-wound infections also improved.²⁰² Streptomycin in a base of carbowax and propylene glycol was found helpful in several cases of persistent infections of the skin around the anus.⁸⁶

In Army hospitals 179 patients with wound infections were treated, with improvement in 72, no improvement in 105 and death in 2.²²⁵ Improvement usually coincided with adequate revision of the wounds, and streptomycin was considered useful only as an adjunct to surgery. One patient with pemphigus was unimproved, whereas 1 case each of generalized furunculosis and acneiform ulcerations improved after neither had responded to penicillin.

Topical streptomycin has been considered superior to penicillin in experimental wound infections because of its wider range of activity under such conditions.¹⁸⁴

Osteomyelitis

Streptomycin may be useful in cases of osteomyelitis in which susceptible gram-negative bacilli predominate, but it seems to be of value mainly as an adjunct to adequate surgery.^{74 254 255} Improvement has been noted in 11 of 15 reported cases.^{74 202, 254, 255} One fatal case due to widespread infection followed the gradual development of resistance by the causative organism, *A. cloacae*.²⁵⁴ In some cases, healing continued despite the development of resistant strains, suggesting that the surgery was an important part of the therapy.²⁵⁵

TUBERCULOSIS

The most extensive studies on the use of streptomycin in clinical tuberculosis thus far reported are those of Hinshaw and his collaborators.^{205 256} They had previously satisfied themselves that this antibiotic was distinctly superior to the sulfones (Promin, Diasone and Promizole) in the treatment of experimental tuberculosis in guinea pigs.^{126 155 156} Another series of cases is under close study by Dr Walsh McDermott at the New York Hospital,²⁰² and isolated cases of tuberculous meningitis have been reported from other clinics.^{70 84 257-260} The report of the National Research Council²⁰² summarized the findings in 87 of these cases. A group of 15 cases was also reported from Army hospitals.²²⁵ A considerable experience is also being accumulated in Veterans Administration hospitals.²⁵¹

Miliary Tuberculosis

The report of the National Research Council²⁰² mentions 7 patients with miliary tuberculosis, all of whom showed regression of the pulmonary lesions on x-ray examination and reduction of fever and systemic signs of infection during streptomycin therapy. Improvement was usually observed within

the first two or three weeks. Three of these patients died, however, and meningitis was observed at autopsy. Of special interest are 2 patients who developed signs of meningitis while receiving intramuscular streptomycin, the meningitis apparently responded after the drug was also given intrathecally. The importance of early diagnosis and persistent treatment with maximum tolerated doses parenterally has been stressed.²⁰⁵ Clinical, x-ray and histopathologic evidences of healing trends have been observed, but no actual cures are as yet reported.²⁰⁵

Tuberculous Meningitis

The results of intensive treatment both intramuscularly and intrathecally for at least four months in this highly fatal disease are somewhat encouraging regarding the possibility of producing arrest of the infection. Parenteral therapy alone appears to be inadequate. The cerebrospinal fluid usually continues to show elevated protein and cell counts, although the values for sugar may become normal after therapy. Serious sequelae, however, have been observed among most of the survivors. The 4 survivors among the 7 patients treated by Hinshaw and his co-workers²⁰⁵ had received intrathecal therapy, — the 3 patients who died had not, — and all had some form of residual neurologic disturbances, thus, one was blind, probably owing to retrobulbar neuritis, one was deaf, possibly as a result of the toxic effects of the streptomycin, the third had profound disturbances of cerebellar function and some mental retardation, and the fourth had paralysis of one of the ocular muscles. In 9 cases reported by others^{70 84 225 257-260} 3 patients recovered, with apparent improvement in the neurologic findings, and the other 6 died.

Pulmonary Tuberculosis

The cases reported were selected chiefly from among those with positive sputums and far advanced or moderately advanced lesions that would be expected to advance under conventional treatment. Streptomycin was given for two to six months in doses of 1 to 3 gm daily. No progression of the disease was noted clinically or on x-ray study in any of the cases during therapy, and even the fatal cases showed some subjective improvement.²⁰⁵ X-ray improvement and negative sputums during treatment were noted in two thirds of the cases, a similar proportion of those with cavities showed closure of these cavities. Reactivation occurred a month after the treatment had been discontinued in 6 of a group of 32 cases, in 3 of which the patients were given a second course, 2 then improved, whereas the third had a rapid progression to a fatal outcome associated with a streptomycin-resistant strain of *Mycobacterium tuberculosis*. There were 4 other deaths, all in far advanced cases.²⁰⁵ In 4 cases treated in Army hospitals, 3 patients were unim-

proved, and 1 with pneumonia was markedly improved²²

Only 4 cases of early infiltrative pulmonary tuberculosis treated with streptomycin have been reported²² These were all in young children with proved tuberculosis On a dosage of 1 gm daily for twenty or thirty days there was clinical and roentgenologic improvement The patients had remained well during a follow-up period of two or three months

Streptomycin may have contributed to the recovery of 7 patients treated with radical surgery for pulmonary tuberculosis²⁰⁵

Renal Tuberculosis

Streptomycin was not considered curative in renal tuberculosis, and bacilluria tended to recur in the advanced cases²⁰⁵ Six out of 14 patients obtained only temporary subjective relief and 8 had a reduction or disappearance of tubercle bacilli from the urine by direct smear^{202 225 263} Only 2, however, had consistently negative guinea-pig tests for prolonged periods In another group of 7 cases, 2 patients were improved and 5 were unimproved²²⁵

Miscellaneous Forms

Six patients with visible ulcerating tuberculous lesions of the upper respiratory tract, trachea and bronchi were treated with streptomycin, all showed healing of the lesions within three to six weeks^{202 225 264} Only 1 of 8 patients with tuberculous empyema showed improvement despite intrapleural injections, with or without intramuscular treatment²⁰² Cutaneous tuberculous fistulas were treated in 15 cases, in 10 of which the fistula closed during therapy and had remained closed for four to ten months²⁰⁵ Prompt healing of a chronic tuberculous sinus in 1 patient occurred with streptomycin therapy²⁶⁵ Three patients with tuberculous peritonitis showed clinical improvement²⁰⁵ Four of 5 patients with tuberculosis of the bones and joints improved under treatment with streptomycin²⁰⁵ Only 1 of 4 patients with lupus vulgaris improved^{205 225}

Histologic Studies

Pathological changes have been studied in 5 patients who died following treatment for tuberculosis with streptomycin over periods of several weeks or longer²⁶⁶ The tuberculous lesions of the spleen, liver and particularly the lungs seemed to be more discrete and less cellular than those seen in untreated cases Many of the lesions were atrophic, fibrotic and hyalinized and showed a minimum of caseation Meningeal lesions were absent in some patients in whose cerebrospinal fluid tubercle bacilli had previously been demonstrated

The consensus regarding the role of streptomycin in the treatment of tuberculosis in human beings is that it exerts a palliative effect by producing

some degree of bacteriostasis The immediate results have been most striking in miliary, meningeal and laryngeal tuberculosis²⁰² The disease requires large doses — about 3 gm daily in adults — for prolonged periods, and treatment should not be undertaken unless adequate amounts of streptomycin are available to permit continuous therapy for at least two to four months It is generally agreed that streptomycin cannot be regarded as a substitute for present methods of sanatorium and surgical therapy^{205 267} Further study of the entire problem of streptomycin therapy in tuberculosis is being sponsored by the American Trudeau Society, the medical section of the National Tuberculosis Association²⁶⁷

TULAREMIA

Streptomycin is particularly efficacious in the treatment of acute tularemia^{202 203 207 225 227 240 — 265-277} It seems to be equally effective against all the acute forms that have been treated — ulceroglandular, typhoidal and pulmonary A comparative study of the treatment of tularemia with immune serum, hyperimmune serum and streptomycin indicates that streptomycin is the therapy of choice in desperately ill patients and that only streptomycin or hyperimmune serum reduces the mean duration of the disease to less than two and a half months if treatment is begun later than the second week of the disease²⁷¹

The report of the Committee on Chemotherapeutics and Other Agents²⁰² includes 67 cases of all types of tularemia, with recovery in 63 There was pulmonary involvement in 11, and the majority of these patients had previously received sulfonamide and penicillin therapy without effect The average dose was only about 10 gm daily for a period of seven days

A series of 11 cases of tularemic pneumonia and 1 case of tularemic pleurisy has been reported in which all the patients showed a prompt clinical response to 0.4 to 1.6 gm daily for six to fourteen days Most of them received 0.5 or 0.6 gm a day for six or seven days One of the patients died suddenly on the seventh day of treatment, presumably of a massive pulmonary embolus the temperature had been normal for four days, and the pulmonary lesion had been regressing *Pasteurella tularensis* disappeared rapidly from the sputum or pleural fluid in all cases It was believed that healing of the pulmonary lesions and the primary ulcers was accelerated, but clinical recovery occurred even more promptly Serum agglutinin titers rose in all cases after treatment, and this rise was marked and rapid in some cases The results were considered to justify a clinical therapeutic trial of streptomycin in doses of 1 to 2 gm daily in cases of severe pneumonia of undetermined etiology occurring where tularemia is endemic²⁷⁷

Three patients were treated with streptomycin because of the persistence of easy fatigability, malaise and intermittent fever several months after an episode of acute tularemia.²⁷⁵ These patients, who were possibly suffering from chronic tularemia infection, showed no improvement in their symptoms and signs

BRUCELLOSIS

Streptomycin has not proved to be of great value in the treatment of brucellosis. Reports of 77 cases, mostly acute infections, are available.^{62, 84, 202, 203, 218, 243, 278-280} Blood cultures were usually negative during treatment, but bacteremia often recurred after therapy had been stopped, and in 1 case persisted during and after the treatment.²⁰³ The effect on the relapse rate remains to be determined, but 2 cases have been reported in which evidence of chronic brucellosis persisted during a follow-up period of one and a half to two years.²⁸¹ The development of a markedly resistant strain of *Br. abortus* occurred during streptomycin treatment in one case of chronic brucellosis.⁶² The possibility of better effects from a combination of sulfadiazine and streptomycin is suggested from results in 2 cases.²⁷⁹

MISCELLANEOUS INFECTIONS

Streptomycin was used in a group of 9 cases of chronic urethritis due to *Neisseria gonorrhoeae* that were clinically resistant to sulfonamide and penicillin therapy.²⁸² 7 cases cleared promptly after a short course of streptomycin consisting of six intramuscular injections of 0.5 gm each. One of the patients, who had prostatic involvement, improved clinically but was not cured, in another, who had chronic epididymitis, smears of the urethral discharge became negative, but the epididymitis did not clear. In another group of 4 previously untreated cases, streptomycin produced a favorable response.²⁸³ Streptomycin is probably indicated for the occasional cases of gonorrhea that prove resistant to sulfonamides and penicillin.

No published reports are available on the use of streptomycin in clinical cases of pertussis. Bradford²¹² found that streptomycin in nose drops (10 mg per cubic centimeter, five drops in each nostril every three hours) or used as an aerosol for three days was effective in eliminating *H. pertussis* from throat cultures. After intramuscular injections negative cultures were not obtained so rapidly as after the local applications.

Malleomyces mallei was eliminated by streptomycin treatment from the skin ulcers of a patient with osseous tuberculosis and secondary glanders.²⁰³

Streptomycin is somewhat effective in experimental spirochetal infections in animals, as noted above in Part I. In a clinical study streptomycin was given in small doses over a ten-day period to

3 patients with early syphilis and to 1 with a gummatous lesion, all improved but later relapsed.²¹⁰

No reports have been found on the use of streptomycin in human viral infections. In 2 patients with typhus fever streptomycin had no effect.²⁰²

One patient with acute pulmonary moniliasis,⁷¹ 1 with blastomycosis of the skin and 1 with a *Cryptococcus hominis* meningitis were treated with streptomycin without effect.²²⁶ No reports are available on the use of the antifungal antibiotic derived from cultures of *Streptomyces griseus* in the treatment of human cases.^{7, 8}

A case of human amebic hepatitis was treated ineffectively with streptomycin.²⁰²

DISEASES OF UNCERTAIN ETIOLOGY

Streptomycin has been used in 29 cases of ulcerative colitis,^{86, 202, 226, 284, 285} with dramatic improvement in only 2 cases,^{284, 285} temporary improvement in 6 and failure to arrest the disease in the remaining 21. In some acute exacerbations the drug sometimes lowered the temperature and seemed to avert a fatal outcome.⁸⁶ No beneficial effect from streptomycin was observed in 6 cases of rheumatoid arthritis,²⁰² 1 case of infectious mononucleosis,²⁰² 1 case of relapsing febrile panniculitis (Weber-Christian's syndrome),²⁰³ 1 case of Hodgkin's disease,²²⁶ and 1 case of Reiter's syndrome.²⁰² Six patients with nonspecific urethritis were treated with streptomycin, 2 were improved, and the remainder were unimproved after several days of therapy.²⁸² Dienes and Kane²⁸⁶ found streptomycin to be of value in some cases of genitourinary infections in which cultures yielded pleuropneumonia-like organisms. They also observed suggestive effects on the course of the disease in cases of Reiter's syndrome. In 13 infants with epidemic diarrhea of undetermined etiology treated with oral streptomycin alone, 10 improved, and 3 died, in at least 4 of these cases survival was attributed to the streptomycin.²²⁶ The drug seemed beneficial in a case of pylethrombophlebitis.²⁸⁷

TOXIC EFFECTS

Although most patients tolerated streptomycin quite well, the drug is not nearly so free of untoward effects as penicillin. Both local and constitutional reactions are frequent, but none have been reported thus far following ingestion, inhalation or local applications to skin and wounds.

Local Reactions

Pain, tenderness and induration at the site of intramuscular injections are quite frequent and are often accompanied by local redness and heat.²⁰² These manifestations may be more frequent and severer with subcutaneous injections. The incorporation of procaine hydrochloride may lessen the discomfort that follows within a few minutes after the injection, but the immediate discomfort may

be minimized if the volume of injected material is kept to a minimum. The use of "pure" crystalline streptomycin sulfate is said to produce only minimal discomfort at the site of injection.²⁰²

In the treatment of meningitis in human beings, intrathecal injections of streptomycin have been attended by few untoward effects, in contrast to the reactions noted in experimental animals.^{155 156} Severe reactions were observed in 5 patients immediately or within nine hours after the first intrathecal or intraventricular injection of 2500 to 100,000 units of streptomycin in concentrations of 10,000 to 20,000 units per cubic centimeter.²⁰⁶ These reactions were characterized by coma and changes in pulse, temperature and respiration. Death from respiratory failure occurred in 2 cases. Since all patients had meningitis, the deaths were not necessarily related to the injections of streptomycin. Early and probably impure lots were used in these cases. Streptomycin given by these routes to many patients with meningitis has been followed by much benefit, without these alarming reactions.^{50 51 119 204}

An increase in meningeal signs or pleocytosis in the cerebrospinal fluid, or both, has been observed.^{7 51 119 206} Fever and pleocytosis may persist in patients recovering from meningitis who are receiving intrathecal streptomycin, but these signs promptly subside when the intrathecal injections are stopped.⁵¹ Even in subjects without meningitis the cerebrospinal fluid may contain 180 to 1500 white cells per cubic millimeter, mostly polymorphonuclears, twenty-four hours after the intrathecal injection of 10 to 20 mg of streptomycin.⁷² These mild reactions should not discourage the use of streptomycin by this route, since the drug is such an important part of the treatment of meningitis.

Constitutional Reactions

Headache, flushing of the skin, nausea, vomiting, a fall in blood pressure and occasionally convulsions were observed immediately following injection of some of the earlier lots of streptomycin.^{69 71 86 202 253} This type of reaction, which is due to a histamine-like impurity in the streptomycin,^{27 289} may be avoided by the use of benadryl,¹⁸³ and probably with pyribenzamine, although the use of the latter has not been reported. Two deaths have been ascribed to this type of reaction following injections of streptomycin.²⁹⁰ Recent lots of streptomycin are relatively free from the histamine-like substance.^{27 202}

Skin eruptions and fever may appear, together or separately, usually between the third and tenth days of streptomycin treatment. The skin lesions may be erythematous, urticarial, maculopapular or hemorrhagic.* Such reactions may recur on subsequent administration. Eosinophilia has been noted with and without the skin rash. Myalgias and arthralgias were noted, especially with some of the earlier batches of streptomycin.^{71 72 85 255} Strepto-

mycin should usually be discontinued if these reactions appear.²⁰²

Probably the most striking untoward effect of streptomycin has been the disturbance of function of the eighth cranial nerve, apparently without relation to the injection of streptomycin into the central nervous system. This effect has been noted with both early and recent batches of streptomycin, suggesting that the effect is not due to an impurity but perhaps represents a selective neurotoxic action of the drug.^{27 289} The incidence of this type of reaction in human beings varies. Only 2 cases of vestibular disturbance were recognized among 706 patients treated in Army hospitals.²²⁵ Absence of vestibular response was noted in 3 of another series of 81 streptomycin-treated patients after average doses of 0.5 gm intramuscularly every four hours for a total of 10 to 50 gm.¹⁸¹ These 3 had complained of dizziness during treatment. The patients treated ranged in age from nineteen to fifty-one years, and those with known ear disease or meningitis were excluded. An additional patient in this group manifested a severe loss of hearing two weeks after treatment but later improved.

Symptoms of eighth-nerve difficulty were reported in 23 cases among those treated at the Mayo Clinic.¹⁵⁰ No patients complained of true objective or subjective vertigo, but they experienced dizziness, light-headedness or giddiness; these symptoms were first noted on change of position. Most of the patients had a positive Romberg test, the imbalance varied from a gentle swaying in all directions to falling in any direction. The patients usually could not walk unassisted. Spontaneous nystagmus, which was noted in 1 patient on change of position, disappeared forty-eight hours after the streptomycin had been stopped. Five of the 23 patients had some loss of hearing, 4 of these 5, however, had tuberculous meningitis. Loss of hearing was noted with daily doses of 3 to 10 gm, but not with 1 or 2 gm. Tinnitus preceded the loss of hearing in all 5 cases. In 3 cases the hearing improved when the streptomycin was stopped or the dose decreased, and in 1 case, deafness recurred when streptomycin was reinstituted. It was therefore believed that streptomycin affected the cochlear apparatus and produced temporary deafness. The loss of vestibular response as judged by caloric and rotation tests has persisted in most of the patients. The patients compensate for this defect, however, by other postural mechanisms so that the symptoms usually persist only for one to three months.^{180 202}

Davenport²⁵¹ reported 90 per cent incidence of vestibular changes in patients treated with streptomycin for tuberculosis, and varying degrees of deafness resulted in a small number of cases.

Toxic effects of streptomycin on the kidneys and livers of experimental animals were described in Part I. No effects on liver or kidney function were noted after single doses of 600 mg intravenously in

*Davenport noted the occurrence of exfoliative dermatitis in 1 case.

6 subjects, and no latent toxic effects were observed in 100 patients given an average total dose of 12.5 gm over a ten-day period.⁶⁹ Abnormal urinary findings and urinary retention were noted with some early and impure lots of streptomycin.^{183, 186, 288} Hyaline and granular casts were found in the urine of 9 of 10 patients receiving crystalline streptomycin, particularly when the urine was acid.²⁰² There was no evidence of renal impairment,^{69, 71, 288} as judged by urea-clearance tests, blood nonprotein nitrogen determinations and concentration-dilution tests. Effects of streptomycin on the kidneys, as manifested by proteinuria, cylindruria, hematuria, and occasionally azotemia, have been noted in another group of patients, but these effects disappeared on withdrawal of the drug.²²⁵ Two cases of acute nephritis have been noted in patients with typhoid fever under treatment with streptomycin.^{213, 291} The role of streptomycin in these cases is not clear.

A diffuse fatty degeneration of the liver was noted at autopsy of a patient who had received streptomycin therapy for miliary tuberculosis, peritonitis and meningitis, but the cause of the liver changes was not clear.¹⁸⁶ No evidence of impairment of the hematopoietic system has been reported by most observers.^{69, 70, 71, 186, 288} Thrombocytopenic purpura occurred during streptomycin treatment of a case of brucellosis and cleared promptly when the antibiotic was withdrawn.²⁹¹

DEVELOPMENT OF BACTERIAL RESISTANCE DURING TREATMENT

The appearance of resistant strains of bacteria has been noted during streptomycin treatment of urinary-tract infections,^{31, 50, 74, 110, 194, 202, 213, 224-226, 240} respiratory-tract infections,^{82, 192} meningitis,^{80, 119, 203} otitis,²²¹ enteric infections (cholera),¹³⁴ biliary-tract infections,^{110, 240} osteomyelitis,^{74, 264} and infections of the skin and wounds.⁷⁴ A wide variety of bacteria that have been observed to acquire resistance to streptomycin in man during therapy include *A. aerogenes*,^{31, 50, 110, 194, 224} *A. cloacae*,²⁵ *Esch. coli*,^{50, 213, 214, 240} a paracolon bacillus,⁵⁰ *Ps. aeruginosa*,^{31, 50, 110, 255} *Pr. vulgaris* (*B. proteus*),^{194, 226} *K. pneumoniae*,^{50, 82} *H. influenzae*,^{50, 82, 119, 203} *V. comma*,¹³⁴ *Myco. tuberculosis* var *hominis*,^{192, 198, 205} *Staph. aureus* and *Staph. albus*,¹¹⁰ alpha-hemolytic and beta-hemolytic streptococci,¹¹⁰ *Str. faecalis*,^{214, 226} *Br. abortus*⁸² and possibly diphtheroids.¹¹⁰

Theories on the development of resistance were discussed in Part I. Regarding the occurrence of this phenomenon clinically, two possible explanations have been offered: either the original pretreatment bacterial population consists of both resistant and susceptible organisms and exposure to streptomycin eliminates the sensitive strains and allows the resistant ones to flourish or the naturally sensitive strains become adapted to the antibiotic in some manner so that they can multiply in its

presence. Naturally resistant strains, including *Esch. coli*, *Pr. vulgaris*, *Ps. aeruginosa*, alpha-hemolytic streptococci and diphtheroids, have been noted.^{82, 89, 110} The usual methods for determining bacterial sensitivity are such that small numbers of naturally resistant organisms may easily be missed. The occurrence or appearance of resistant strains in man during streptomycin therapy is important because it may seriously interfere with the efficacy of the treatment.

Alkalinization of the urine during streptomycin therapy⁸⁶ may offer a means of limiting the development of resistant strains of organisms in some cases of urinary-tract infection. The use of large initial doses of streptomycin in an attempt to avoid exposure of the organisms to subinhibitory concentrations of the drug seems logical and has been suggested.^{202, 214-216, 228, 289} Yet even when large doses of streptomycin were given initially, resistant strains of bacteria sometimes developed, particularly when the reaction of the urine was acid.⁵⁰

In cases of tuberculosis, resistant strains may not become apparent until after several weeks or months of treatment. Tubercle bacilli obtained from such cases are equally resistant when cultured directly from sputum, urine or gastric aspirations, from such cultures after storage in a refrigerator or when the cultures are made from infected organs of guinea pigs inoculated ten or more weeks previously with material from the patient and when subsequently maintained on glycerine egg agar for several weeks.¹⁹¹ The implications of these observations regarding the possibility of streptomycin therapy in cases of cross-infection or laboratory infection with such strains are obvious.

Just how long resistant strains may persist in the patient once they have appeared during therapy is not known. In some patients treated for chronic urinary-tract infections, such resistant strains were demonstrated for several months⁸⁶ and in 1 case, for as long as eleven months.¹¹⁷

SUMMARY

Streptomycin has proved most effective in acute tularemia and in cases of meningitis due to gram-negative bacilli, especially *Haemophilus influenzae*. It is useful in most gram-negative bacillus infections, particularly those of the urinary and respiratory tracts. The results in some forms of tuberculosis are encouraging, and it is at present the best available chemotherapeutic agent for tuberculous infections. Typhoid fever, *Salmonella* infections and brucellosis have not responded favorably. It may be useful as a second line of defense in some cases of coccal infections that prove insensitive to the sulfonamides and penicillin or develop fastness to these agents.

The greatest limitation to the clinical usefulness of streptomycin is the readiness with which most organisms develop resistance to it.

Streptomycin is relatively nontoxic. The most serious untoward effect that has been noted is a disturbance in vestibular function. This effect has been observed mainly following the use of large amounts of the drug over prolonged periods.

Streptomycin is a valuable addition to the group of agents that are used for the definitive treatment of infectious diseases, particularly since it is effective in some infections that are influenced little, if at all, by other available agents.

BENJAMIN CASTLEMAN, M D, *Associate Editor*

EDITH E PARRIS, *Assistant Editor*

CASE 33201

PRESENTATION OF CASE

First admission A fifty-six-year-old housewife entered the hospital complaining of abdominal pain and vomiting

The patient had been in excellent health until two years previously, when she first began to have periodic bouts of nausea and vomiting accompanied by a dull pain in the left upper quadrant. At first the attacks occurred every four or five weeks and lasted for one day. The vomitus was composed of stomach contents with no blood or bile. There was no particular relation to the intake or type of food. During the intervals between attacks she felt well, and the appetite remained normal. After several months, however, she noticed some weight loss. The attacks increased in frequency and severity so that she was admitted to another hospital for study, where a gastrointestinal and a gall-bladder series, as well as a barium enema, were negative. A diagnosis of anemia was made, and liver injections were given for a few months. Nevertheless, she remained unimproved and was forced to eliminate many foods from the diet in an effort to control the pain and vomiting. A "yellow color" developed eighteen months before admission but cleared slowly while iron and weekly injections of liver extract were being given. Then followed a period during which the vomiting and pain subsided, although the patient continued to lose weight. During the following year the attacks recurred, and many studies, including

x-ray films, were done, none of which revealed any abnormality other than anemia. Six months prior to admission the skin became "brownish" for a few weeks. At that time the systolic blood pressure was 86. She was given "injections" and ten salt tablets daily, but after five weeks she became extremely edematous and the treatment was stopped. The attacks of pain grew more frequent and at the time of admission were of daily occurrence. She had limited the food in amount and to soft solids and fluids. Most of the attacks of pain, which were described as dull and nagging, came on after meals, arose in the left upper quadrant and radiated across the abdomen to the right. Although the patient often became extremely hungry, she could eat only a few mouthfuls of food and on several occasions "fainted from hunger." The weight had fallen from 175 to 113 pounds, and the nausea and vomiting had become infrequent. She had gradually become constipated during the second year of the illness so that she required a laxative almost daily. There had been no tarry stools.

Physical examination revealed a well developed but pale and emaciated woman in no acute distress. The skin was dry, with poor turgor. Examination of the heart and lungs was negative. There was considerable spasm of the abdominal wall, with an irregular area of marked tenderness immediately to the left of the umbilicus. No masses were palpated. Pelvic examination was negative.

The temperature was 99.4°F, the pulse 86, and the respirations 20. The blood pressure was 88 systolic, 48 diastolic.

X-ray examination of the chest, as well as an intravenous pyelogram, a Graham test and examinations with a barium meal and enema were negative.

Examination of the blood showed a red-cell count of 2,820,000, with a hemoglobin of 4.6 gm, a hematocrit of 20 and a cell volume of 71 cu microns. A blood smear revealed a marked achromia with some variation in size and shape of the cells. A fragility test was negative. The reticulocyte count was 1.2 per cent, and the white-cell count 13,000, with 80 per cent neutrophils. The urine showed a specific gravity of 1.008, a ++ test for albumin and no sugar. Bence-Jones protein was absent. Several

stools were brown and guaiac negative. The non-protein nitrogen was 25 mg, the protein 6.8 gm and the sugar 107 mg per 100 cc. Gastric analysis showed free hydrochloric acid.

One examiner believed that he felt an irregular mass to the left of the umbilicus and suggested pentoneoscopy. This was done on the tenth hospital day. No masses were visible anywhere in the peritoneal cavity or in the pelvis. The uterus and ovaries were not abnormal. The liver appeared normal and extended three or four fingerbreadths below the costal margin. A liver biopsy was taken during this procedure, and microscopical examination showed no abnormality. The patient was discharged on the eighteenth hospital day.

Final admission (two months later). During the following two months the symptoms continued essentially unchanged. The patient remained on a bland diet, taking iron and vitamins.

X-ray examination showed the stomach to be somewhat dilated, with increased peristalsis. The barium passed readily through the pylorus into the first and second portions of the duodenum, where there was some dilatation. In spite of the increased peristalsis there was a marked delay at this point. There was regurgitation from the duodenum back into the stomach, and only a small quantity of barium passed around the duodenal loop during fluoroscopic examination. Two hours later most of the barium was still in the stomach and duodenum, and only a small quantity had reached the lower jejunum. Six hours after fluoroscopy there was little change. Further examination showed an area of ulceration, 3.5 cm in diameter, in the upper jejunum. The lumen was irregularly dilated. A number of loops appeared to be adherent, and a mass corresponding to the lesion in the bowel was palpated.

Three transfusions were given, and an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR BERNARD M. JACOBSON. This is undoubtedly a case of small-bowel obstruction probably extending over a period of two years. Since I am on the medical service, I am indeed flattered to be presented with such a case. I shall try to uphold the honor of that service in making the diagnosis. I am sure, however, that there are several points about the diagnosis that I shall miss entirely.

The record states that the patient had anemia eighteen months before the first admission. Although she received liver injections for a few months, I believe that the later evidence is sufficient to rule out a liver-deficiency anemia. Certainly, the appearance of the blood is not that of pernicious anemia. The presence of free hydrochloric acid is additional evidence against pernicious anemia, as is the fact

that a course of liver injections gave no improvement.

A yellow color developed and cleared slowly. I have no idea what this was. It may have been due to a common-duct obstruction, which I do not believe has any relation to the present illness. We are reminded on several occasions that she continued to lose weight despite a fair appetite and despite the subsidence of vomiting and pain. One begins to wonder about malabsorption of food or food products due to diffuse small-bowel disease of some sort. We are told that six months before admission, the systolic blood pressure was 86, that the skin was brownish and that some sort of injections and ten salt tablets daily were given. On the basis of these data it is difficult to make a diagnosis of Addison's disease. The record contains no reference to pigmentation of the skin or mucous membranes and no statement regarding chemical investigation of the electrolytes; there is also no later mention of treatment for Addison's disease. The fact that the patient became edematous indicates overdosage of desoxycorticosterone acetate. During the course, no note is made of the passage of a Miller-Abbott tube for diagnostic purposes in conjunction with the x-ray studies. One wonders why that procedure was not done at the time of the first admission, in view of a history suggestive of small-bowel obstruction. Was a Miller-Abbott tube passed?

DR TRACY B. MALLORY. No.

DR JACOBSON. The blood studies indicate a moderately severe hypochromic microcytic anemia. This anemia was the nondescript type that is observed in a large variety of conditions. The normal fragility test and reticulocyte count and the lack of icterus are evidence against the presence of hemolytic anemia, and the normal reticulocyte count is also against the presence of a recent severe intestinal hemorrhage. On the other hand, long-continued oozing of blood can occur in small amounts without a high reticulocyte count as evidence of regeneration in the bone marrow. The figures do not suggest a primary blood dyscrasia, such as leukemia or aplastic anemia. I might add that I do not believe I shall ever be able to explain the anemia properly. I have seen several patients with tumor of the small or large bowel in whom there was no history of frank bleeding, with guaiac-negative stools, and in whom a similar anemia was fairly resistant to treatment. I do not believe that we can rule out occasional slow oozing in this patient, and yet we have no evidence for it. The serum protein of 6.8 gm per 100 cc is rather high for a person with severe anemia, and assuming that she was not dehydrated when the blood was taken, I wonder if we are dealing with one of the several conditions that cause hyperproteinemia. There is certainly no evidence of the most frequent condition that occurs with anemia—namely, myeloma. On the

other hand, it must be remembered that a small proportion of other types of lesions, such as granulomas, do show high serum proteins. It is interesting that peritoneoscopy at the first admission revealed no masses in the abdomen. Peritoneoscopy was informative certainly in that the liver biopsy ruled out amyloid disease, which is one of the conditions that the record suggests.

May we see the x-ray films taken at the time of the final admission?

DR STANLEY M. WYMAN: The first film was taken at the first admission and shows a normal-appearing stomach, duodenal cap and duodenal loop. No abnormal masses can be seen. A review of the films of the first admission suggests some irregularity in the region of the small intestine. The film taken during the second admission shows the irregularity described somewhat better, and it appears to be a filling defect of the lumen of the small intestine. The exact contour cannot be well outlined. The mucosal pattern in this region is no longer present.

DR WALTER BAUER: You have no hesitancy in saying that the mucosa is ulcerated?

DR WYMAN: I believe that it is.

DR JACOBSON: Is there anything that looks like pipestem infiltration in the small bowel?

DR WYMAN: A sclerosing process? I do not believe so.

DR JACOBSON: The ulcerating process and the obvious x-ray evidence of obstruction in the upper part of the small intestine compel me to consider the differential diagnosis of obstruction. Inasmuch as we are told that there was an area of ulceration in the mucosa, the differential diagnosis becomes considerably limited. As I look back over the case, the period of two years with similar symptoms makes it seem logical to assume that this was a tumor, either benign or possibly mildly malignant, that started either in the lymphoid patches or the muscularis and gradually became larger, penetrating into the lumen and involving the serosa and extraintestinal tissues. I do not believe that there are many tumors that can present these symptoms over a period of two years. Certainly the location of the palpable mass in the abdomen is consistent with the location of this lesion somewhere in the jejunum. I should like to characterize the behavior of the tumor for two years by calling it a lymphosarcoma that probably showed, at an early stage, some intraluminal protrusion and caused the early symptoms of pain and vomiting and obstruction, possibly through the mechanism of repeated intussusception. It is only later in the patient's course that we have evidence that the tumor began to ulcerate. I believe that this tumor had grown outward, adhering to many coils of the small intestine, and had finally begun to present a mass that could be felt. I suspect that the lesion was much more extensive in the small bowel than the x-ray evidence indicated. The

extensiveness of the tumor was due to the early presence of malnutrition, possible malabsorption of certain food stuffs and the early presence of a severe refractory anemia. Possibly, the serum protein of 6.8 gm was caused by a lymphosarcoma, which occurs in some cases, but I do not want to stress the importance of any one laboratory finding of that sort. There were undoubtedly metastases to the mesenteric lymph nodes. I am not completely satisfied with the explanation of the anemia or of the hypotension, the yellow color eighteen months previously and the more recent history of a brownish color. My diagnosis is lymphosarcoma of the jejunum with regional intestinal involvement and ulceration of the mucosa.

A PHYSICIAN: How about the pancreas?

DR JACOBSON: In view of the ulceration of the mucous membrane of the jejunum on x-ray examination it seems to me that the tumor probably arose from the small intestine rather than from extraintestinal structures.

CLINICAL DIAGNOSIS

Carcinoma of jejunum

DR JACOBSON'S DIAGNOSIS

Lymphosarcoma of jejunum

ANATOMICAL DIAGNOSIS

Adenocarcinoma of jejunum

PATHOLOGICAL DISCUSSION

DR MALLORY: This patient was operated on by Dr Sweet. I am sorry that he is not here to describe his findings at first hand. A large tumor of the jejunum was found within 10 cm of the ligament of Treitz. The tumor involved the wall of the bowel and the adjacent mesentery and had seeded itself on another loop of jejunum, which had become adherent to it. At operation it had evidently been extremely difficult to preserve the blood supply of the transverse colon, but it was possible to resect the two loops of intestine and the large mass in the mesentery.

The specimen in the laboratory was an ulcerated tumor of the jejunum on the mesenteric side that did not completely encircle the bowel. The major mass of tumor lay in the mesentery and was 6 to 7 cm in diameter. On microscopical examination it turned out to be a well differentiated, slowly growing adenocarcinoma of the jejunum. Cancers of the small bowel are relatively rare, but they do occur from time to time.

DR JACOBSON: How much of the jejunum was actually involved?

DR MALLORY: A small amount of jejunum was directly involved by the tumor, but the links and the adhesions may have thrown a considerable portion more or less out of function.

CASE 33202

PRESENTATION OF CASE

A seventy-eight-year-old widow entered the hospital from a home for the aged complaining of severe abdominal pain and vomiting.

She had been well until three days previously, when, after a normal meal, she began to have intense, cramping abdominal pain in the midepigastrium with vomiting. Following this attack she continued to have intermittent sharp cramping pains radiating across the midabdomen every two to five minutes. Occasionally, the pain was referred to the back but never to the shoulder or the interscapular region. She could take nothing by mouth without vomiting, the vomitus often consisting of greenish, foul-smelling material. There had been no bowel movements or passage of gas during the five days before admission. Two enemas as well as a laxative, had been given without result. The patient's general health had been good until the abrupt onset of the illness. She had lost no weight, and the bowels had moved regularly without evidence of blood or tarry stools. Two months previously a similar episode of vomiting had lasted only a few hours and had been relieved by bicarbonate of soda.

The past history revealed that both femoral necks had been fractured in falls — the right eight years, and the left eight months previously. Both fractures had been successfully treated by nailing. There had been no abdominal operations or pregnancies.

Physical examination revealed a slightly obese woman in no acute distress. The skin was moderately dehydrated without evidence of cyanosis or jaundice. The lungs were clear. The heart was somewhat enlarged on percussion. No murmurs were heard. The abdomen was diffusely tender without spasm, distention or palpable masses. The liver and spleen were not palpable. Pelvic examination was negative.

The temperature was 99.5°F, the pulse 80, and the respirations 30. The blood pressure was 130 systolic, 90 diastolic.

A plain film of the abdomen showed several gas-filled and fluid-filled loops of what appeared to be small bowel. No gas was seen in the colon. X-ray films of the chest were normal.

Examination of the blood revealed a hemoglobin of 16.5 gm and a white-cell count of 12,500, with 60 per cent neutrophils. The urine showed a specific gravity of 1.012, a +++ test for albumin and no sugar or bile. The nonprotein nitrogen was 28 mg, the protein 8.0 gm, and the fasting blood sugar 149 mg per 100 cc, and the chloride was 98 milliequiv per liter. The serum amylase was 14 units. The van den Bergh reaction was 0.7 mg per 100 cc direct and 1.0 mg indirect.

A Miller-Abbott tube was introduced, and intravenous fluids with dextrose and Amigen were ad-

ministered daily. The patient continued to have occasional bouts of cramping abdominal pain. On the third hospital day a prophylactic bilateral femoral-vein interruption was done. The progress of the Miller-Abbott tube was followed by daily x-ray study. The tube progressed slowly through the proximal small bowel, several loops of dilated small bowel being noted distal to the advancing tip. By the seventh hospital day the tube had reached the distal ileum. At that time a single loop of dilated small bowel was seen on the left in the mid-abdomen. A barium enema done on this day showed a good flow, without hesitation, to the cecum through a spastic colon. Numerous diverticula were noted throughout the colon. The terminal ileum was not seen. Several linear shadows were found in the right upper quadrant and were thought to outline the biliary tree. An overexposed film taken to clarify the situation in this area showed gas outlining the stomach and the duodenal cap. Overlying the latter shadow were several irregular linear collections of opaque material whose location was uncertain but was thought to be in the biliary tree. There appeared to be gas in a thin, branching channel extending upward from the location of the duodenal cap.

During the second week of hospitalization there were periods of freedom from pain. The patient passed several stools, consisting mostly of barium, and occasionally passed some gas. She remained essentially unchanged, however, with recurring pain, slight distention and some hyperactive peristalsis.

On the nineteenth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR EDWARD HAMLIN, JR. May we see the x-ray films?

DR STANLEY M. WYMAN. The chest films are essentially those of a woman with a moderately large heart, there is nothing specific about the picture. This next film shows the dilated small intestine and the Miller-Abbott tube starting down through the stomach. In a later examination a branching pattern of what seem to be gas-filled tubes is outlined in the right upper quadrant overlying the shadow of the liver. At the same time linear collections of increased density, apparently barium, lie in the region of the duodenal cap. These are the diverticula in the colon.

DR HAMLIN. Was barium given by mouth at any time?

DR WYMAN. I believe that she was given one small swallow of barium.

DR HAMLIN. That is important because otherwise it would be difficult to determine how barium reached the small bowel.

Can you demonstrate the air-filled biliary tree?

DR WYMAN I think that it is best seen in this film. This looks like the common duct, with shadows representing branching hepatic radicles.

DR HAMLIN The problem is one of an elderly person who obviously had small-bowel obstruction, probably not entirely complete. I say that because at entry, after difficulty for five days, there was relatively less evidence of small-bowel dilatation than she had later when she was being treated more adequately. In the later stage gas passed through when the Miller-Abbott tube was down, so that obstruction was not complete all the time.

The causes of small-bowel obstruction are many. The fact that there had been no previous operations is important. The patient was slightly old to have had congenital bands or adhesions, although I suppose that either diagnosis is a possibility. There is nothing in the x-ray picture to lead one to believe that she had volvulus of any sort, nor does the history suggest it. The lead that is given in the protocol, concerning the outline of the biliary radicles, cannot be ignored for obvious reasons, and immediately one thinks of gallstone ileus. I am going to believe that she had that without any question.

It is of interest to discuss an elderly person with dehydration and the treatment of obstruction. Several years ago Dr McKittick and I effectively demonstrated that in a patient with intestinal obstruction who is seen within the first twenty-four hours and in whom operation is done at once, the mortality rate will approach zero. If the patient is seen after the first twenty-four hours the hazard of anoxemia of a section of bowel is probably less than that of operation with the dilated loops of bowel that would be present. The treatment of this patient followed Dr McKittick's teaching in that she was hydrated, a Miller-Abbott tube was passed and kept down until the bowel was considerably less dilated, and the operation presumably was a fairly easy one and far less hazardous for her than if it had been done in the earlier period. To carry out this type of preoperative treatment is extremely important. Why it required nineteen days, I do not know. I think that the service deserves considerable credit for keeping her in an electrolytic and fluid balance for that period.

Gallstone ileus is a relatively rare condition, consisting of a large gallstone that produces inflammatory adhesions between the gall bladder and the small bowel. Gradually the gallstone passes into the lumen of the small intestine. Because of the large size of the stone, it is almost invariably found at the terminal ileum. The obstruction is almost always complete.

CLINICAL DIAGNOSIS

Gallstone ileus?

Band adhesion obstruction secondary to old diverticulitis?

DR HAMLIN'S DIAGNOSIS

Gallstone ileus

ANATOMICAL DIAGNOSIS

Gallstone ileus

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY Dr Risley, will you describe the operative findings?

DR THOMAS S RISLEY As Dr Hamlin prophesied, at operation a gallstone was found, but not at the ileocecal valve. It was somewhere in the midileum. There was no necrosis of the bowel at the site of the stone, and there was no obvious reason why the stone should have stopped at that particular point. The stone was movable, and it was relatively simple to milk it upward to a point above, where the bowel was more normal in appearance. It was pushed back several feet above the point where the bowel was edematous and dilated and palpable. There were numerous adhesions in the upper quadrant, but no stones were

DR MALLORY The region was not explored.

DR LAURENCE L ROBBINS, have you ever been able to demonstrate stones in the small bowel? have, but of course certainly. Occasionally, we find little calcium that such a demonstration is often impossible. I believe that in this case the stone following removal showed a few flecks of calcium, but we were never able to identify a film of the ordinary films.

DR MALLORY A gallstone that produces obstruction in the small bowel must be large, and gallstones consist chiefly of cholesterol and contain little calcium. One would not expect a high percentage of them to show roentgenologically.

As Dr Hamlin pointed out, this kind of stone is too large to go through biliary passages of normal size. The chances are at least nine out of ten that there is a fistula between the gall bladder and the intestinal tract through which the stone passed. That was not demonstrated in this case because the patient was old and had had intestinal obstruction for a long period, so that extensive exploration was probably not considered to be justified.

DR BENJAMIN CASTLEMAN How often have you seen gallstone ileus with carcinoma?

DR. MALLORY I do not remember having seen it

DR. BERNARD M. JACOBSON How large does the stone have to be?

DR. MALLORY This one was 3 cm in diameter

DR. WALTER BAUER We had one a few years ago that was found during a gastrointestinal series — a barium-filled, instead of an air-filled, biliary tract

DR. FLETCHER H. COLBY The delay of nineteen days is interesting. Why was operation delayed?

DR. RISLEY The obstruction was quite incomplete, and it appeared at one time as if the obstruction would be spontaneously relieved. It was thought that if the patient had a gallstone she might pass it. She was in poor condition, and it was hoped that the exploration might not be necessary. She was given a trial with removal of the Miller-Abbott tube and had a normal bowel movement, and it

looked briefly as if the obstruction had been relieved; shortly after removal of the tube, however, she became obstructed once more. The first obstruction required quite a time for sufficient decompression to make exploration easy, and the same situation was encountered with the second obstruction.

DR. MALLORY It is of interest that a patient can have such severe disease of the biliary tract as this patient must have had with nothing in the past history to suggest such a condition. She had been in the hospital on two or three previous occasions, and at no time did she complain of symptoms referable to the biliary tract.

DR. BAUER Is that unusual? The incidence of gallstones at autopsy is high, is it not?

DR. MALLORY Yes, but not in association with ulcerative cholecystitis.

STREPTOMYCIN

STREPTOMYCIN has been generally available to the medical profession of this country for several months, and by now, most physicians, particularly those who are privileged to treat or to follow the course of patients in hospitals, have had the opportunity of observing the use of streptomycin in occasional patients of their own or of their colleagues. A considerable literature dealing with this antibiotic has also accumulated, and many clinical reports have become available, particularly during the past year. Many additional reports of its use will undoubtedly continue to appear in the near future. A fairly thorough review of the available literature on this topic is presented in this issue and in the preceding issue of the *Journal*.

Streptomycin, as pointed out in this review, has not lived up to all that was expected of it when it first made its appearance. Perhaps the profession had been led to expect too much because of the brilliant results that had so recently been achieved with penicillin. It has, however, proved quite useful, and without doubt, many persons already owe their recovery from various serious infections to treatment with streptomycin. It has provided an effective cure for certain infections for which other available antibacterial agents have not proved successful and offers an alternative or additional agent in some infections that are only partially affected by sulfonamides, penicillin or specific immune serums. It is the first agent to receive careful and extensive study in the treatment of tuberculosis, with some promise of at least limited success.

The exact place that streptomycin will occupy in the treatment of infections, particularly tuberculosis, cannot be predicted at this time. Its greatest disadvantage has proved to be the great ease with which resistant strains become established during the course of treatment. This alone may eventually limit, if not entirely vitiate, its usefulness in tuberculosis and in other infections, particularly those whose courses tend to be subacute or chronic. Its toxicity, although not of a high order, is significant. This is particularly true of the otic complications, which seem to be caused by the antibiotic itself and not by any impurity and which may leave serious and possibly permanent damage. Moreover, the treatment is expensive by any standard, and is likely to remain so. This is bound to be an important deterrent to its widespread use, particularly in view of its other limitations.

These facts justify a sustained and intensive effort to discover new, more potent and more widely effective chemotherapeutic and antibiotic agents. The discovery of the chemical structures of penicillin and streptomycin and the recent advances in the knowledge of bacterial metabolism in relation to chemotherapy offer considerable hope for synthesis of such agents in the not too distant future. In the meantime, the best use should be made of the agents that are now available.

FULL UTILIZATION OF HOSPITAL FACILITIES

A LETTER dealing with certain aspects of hospitalization appears elsewhere in this issue of the *Journal*. The correspondent's points are well taken, and from a businessman's point of view, it certainly is a waste of time and of invested capital to have facilities such as the operating room and the x-ray and laboratory departments functioning only part time. That this results in a great waste of bed days so far as the total number of patients is concerned is unquestionable. On the other hand, if beds are filled

at all times, it seems reasonable to assume that the revenue to most financially embarrassed hospitals would not be appreciably greater whether the occupant of the individual bed changed every seven days or every fourteen. Fees for specific services would increase, but this would probably be counterbalanced by the cost of the necessary additional personnel. There would, however, be a decrease in the unit overhead cost, which in institutions such as the large teaching hospitals might result in considerable saving.

Regardless of the financial considerations, in these difficult days it is essential that hospital facilities should be used for the greatest good for the greatest number, indeed, about a year ago the need of a "seven-day week" was commented on editorially in the *Journal**. The fact is inescapable that if a patient is occupying a hospital bed unnecessarily long it is a waste, and it is suggested that all hospitals, whether privately endowed or financed by community, state or nation, should seriously consider a change from a method of operation that results in such an obvious loss of urgently needed facilities.

MASSACHUSETTS MEDICAL SOCIETY DEATHS

BOYLE — John F. Boyle, M.D., of Lowell, died April 25. He was in his seventy-sixth year.
Dr. Boyle received his degree from Harvard Medical School in 1903. He was a former president of the Middlesex North District Medical Society and was a member of the New England Obstetrical and Gynecological Society.
A sister survives.

CARSLEY — Sidney R. Carsley, M.D., of Palmer, died April 19. He was in his seventy-second year.

Dr. Carsley received his degree from University of Vermont College of Medicine in 1902. He was medical examiner for the Eastern Hampden District and was a member of the staffs of the Mary Lane Hospital, Ware, and the Springfield Hospital. He was a fellow of the American Medical Association.

His widow and a son survive.

CASWELL — Bertram H. Caswell, M.D., of Somerville, died April 14. He was in his seventy-second year.

Dr. Caswell received his degree from Tufts College Medical School in 1903. During World War I he served as a captain in the Army Medical Corps. He was a member of the New England Otological and Laryngological Society and a fellow of the American Medical Association.

His widow and a step-daughter survive.

HUNT — William O. Hunt, M.D., of North Falmouth, died April 19. He was in his ninety-third year.

Dr. Hunt received his degree from Harvard Medical School in 1877. He was the last surviving founder of Newton Hospital. Until his retirement from active practice in 1940, he had practiced medicine in Newtonville for fifty-nine years.

A daughter, four sons (one of whom, Dr. Harold O. Hunt, is a resident of North Falmouth), thirteen grandchildren and five great-grandchildren survive.

RONEY — Hugh B. Roney, M.D., of Pittsfield, died January 8. He was in his sixty-first year.

Dr. Roney received his degree from Hahnemann Medical College and Hospital of Philadelphia in 1909. He was a member of the staffs of the House of Mercy and Hillcrest hospitals, Pittsfield.

MISCELLANY

NEW MEDICAL DEAN AT BOSTON UNIVERSITY

Dr. James M. Faulkner, director of the First and Third Medical Services, Boston City Hospital, and professor of medicine at the Tufts College Medical School, has been appointed dean of Boston University School of Medicine. Dr. Faulkner will succeed Dr. Donald G. Anderson, who has resigned as of June 1, to accept a position as secretary of the Council on Medical Education and Hospitals of the American Medical Association in Chicago.

Dr. Faulkner, the son of the late Dr. Herbert K. Faulkner, of Keene, New Hampshire, graduated from Harvard College and Harvard Medical School, and received training at the Massachusetts General Hospital, Rockefeller Institute for Medical Research and Johns Hopkins Hospital. He was associated with the Harvard Medical School at Thorndike Memorial Laboratory of the Boston City Hospital for ten years, being in charge of the Electrocardiographic Laboratory. He later joined the staff of the Boston University School of Medicine and the Massachusetts Memorial Hospitals, where he was in charge of the cardiac clinics.

Dr. Faulkner served in the Navy during the war, being in charge of the medical service at an English base hospital that cared for patients evacuated from the Normandy beach head. He received a commendation from Admiral Stark for this work, and attained the rank of captain before his discharge.

PASSANO FOUNDATION AWARD

Selection of Dr. Selman A. Waksman, microbiologist at the New Jersey Agricultural Experiment Station, New Brunswick, New Jersey, as the 1947 recipient of the Passano Foundation Award has recently been announced by the Board of Directors of the Foundation. Established in 1943 by Williams & Wilkins Company, medical publishers, of Balti-

more, the Foundation proposes to encourage medical research, especially that which has clinical application, and has established the award as one of its activities. Dr Waksman receives the award for his original research in the field of antibiotics culminating with his discovery of streptomycin, which among its many uses gives promise of being of value in the successful treatment of tuberculosis.

Presentation of the \$5000 cash award will be made at a dinner to be attended by about a hundred outstanding medical men at the Ritz-Carlton Hotel, Atlantic City, on Thursday evening, June 12, during the week of the centennial meeting of the American Medical Association. Sir Howard Florey, of Oxford, England, who was knighted for his development of the clinical applications of penicillin, will make a brief address, following which the award will be presented to Dr Waksman. Dr Waksman's address will be entitled "Antibiotics and Tuberculosis — a Microbiological Approach."

NOTE

Dr Robert P Knight, at present chief-of-staff of the Menninger Clinic, Topeka, Kansas, has recently been appointed medical director of the Austen Riggs Foundation, Stockbridge, Massachusetts. Dr Edgerton McC Howard, who is now serving as acting medical director, will become associate medical director. Dr Knight will assume his new duties on September 1.

CORRESPONDENCE

"THE LOST WEEK-END"

To the Editor Hospitals today are badly overcrowded and have long waiting lists. Emergency surgical patients are readily admitted in most instances, a spare room or bed is usually reserved for just such a contingency or a temporary arrangement is made, such as placing the patient, even though of private status, in a ward. A medical emergency fares less satisfactorily, and patients who present no emergency but who are ailing and require the facilities of a hospital for diagnosis are placed on the waiting list and have a poor chance of being admitted for weeks or months.

The chief reasons for crowded hospitals appear to be the following: (1) The Blue Cross, the Blue Shield and other types of hospital and medical insurance, which permit benefit if the patient is hospitalized, (2) the widespread use of penicillin, which, to be given effectively, usually requires hospitalization, (3) the scarcity of trained nurses for home duty, (4) the shortage in the hospitals of nursing personnel and technicians, (5) the increased cost of operating hospitals in such a way that they function properly, and (6) the common custom of hospitals to run at low speed during week ends and holidays. The last reason is, in my opinion, an extremely important one. At such times the nursing and technical departments are manned by skeleton crews, which attempt to function only on an emergency basis. Out-patient departments are closed, although there is no doubt that if they were open not only would many be helped who would otherwise hesitate to seek help because of the fear of losing a day's work and pay but also advice would be given to others that might later forestall serious illness for which hospitalization and abstinence from work would become imperative.

As a direct result of the above factors patients are obliged to remain in the hospital, often at great expense to themselves or to industry, to wait their turn for the various special examinations ordered by the physician. A patient who enters the hospital Friday afternoon and who pays \$7 a day on the ward or \$10 or more a day for a private room, does not relish the knowledge that only emergency work will be done for him until Monday and that even some of the work that has to be done may not be reported till Tuesday.

Faced with this unprecedented demand for admissions, what steps have the hospitals taken? They have appealed for more nurses to keep their wards open, and they have raised salaries. It seems to me the one step not taken to increase their usefulness is to eliminate the week-end or holiday vacation. Were this latter step taken, an extra one and a half days would become available weekly for routine hospital diagnostic procedures. Thus approximately a week would be

gained monthly, or seventy-five days yearly, which, added to about eight days for holidays, would amount to nearly three months each year. In this manner, the capacity of the hospital, in so far as routine diagnostic procedures are concerned, would be increased by about a third.

How can the hospital provide for the full-time use of facilities? Obviously, it will be necessary to increase the personnel and to stagger the working hours. A further raise in salaries may be required. To provide for additional medical personnel, it might be possible to arrange for so-called "floaters." Thus, a private roentgenologist might be induced to "spell" his resident brother for a week end or for a specific number of hours each week. The same would be true of the pathologist, anesthetist and so forth. This problem would not differ materially from that of arranging for the summer vacation or for prolonged illness.

The money necessary to run the hospital on this full time schedule would become available from the increased income obtained by the more rapid turnover of patients. In addition, as the improved facilities and service offered by the hospital impressed the community, there would be a greater eagerness to contribute to its support.

PROFESSIONAL RESPONSIBILITY

To the Editor In reference to Dr Stratton's statement in the March 20 issue of the *Journal* regarding my recent experience with the Court, I wish to present to the fellows of the Massachusetts Medical Society the facts of the case.

On the morning of February 16, at about 2:00 a.m., I was called to see a young woman who had been criminally attacked. The car in which she and her escort were riding had been stopped by blocking the road, the door window smashed, her escort ordered out by two masked men at gun point, the girl taken out by a third man at gun point and then criminally attacked by the three men in turn.

I was fully satisfied that the girl's story was true, and examination showed unmistakable evidence of assault. Her family made it plain that they wished nothing said of the matter and refused to consult the police. I agreed that it was a private matter and that, so far as I was concerned, their wishes would be respected.

On my return home, however, and on reflection of the incident, I decided that, for the protection of the public, the police should be notified of the affair. That same morning I gave all the details, excepting names, to the police and informed them that I was doing this without the patient's knowledge and against the expressed wish of her family.

Two weeks later, a young man was killed when two gunmen ordered him and his girl companion into the back seat of his car and took possession of the machine. The police then asked me for the identity of the young lady whom I had treated, on the supposition that this murder might have been committed by the same men who had assaulted her.

When permission was sought from the family for police questioning, they took the attitude that I had broken faith with them by reporting the incident. I told them that I had done so for the protection of the public and reminded them that I had not revealed the girl's identity and would not do so without their permission. They steadfastly refused to give the consent requested.

On my refusal to reveal the identity of the girl to the Grand Jury on professional grounds, I was jailed. The girl's family then came forward and arranged with the State Police for the questioning of the girl and her escort to effect my release.

I believe that it is unfortunate that, under existing Massachusetts statutes, a physician has only the Oath of Hippocrates as justification for keeping a pledge of privacy given to a victimized patient. I respectfully ask that the Committee on Legislation consider the desirability of effecting an amendment of the present law to grant to physicians the privilege that the public assumes we already possess and that is recognized by law in New York, Pennsylvania and many other states.

CHARLES L BRENNAN, M.D.

Lowell, Massachusetts

TREATMENT OF HERPES ZOSTER WITH SULFADIAZINE

To the Editor I have seen no mention in the literature of the use of the sulfonamides in the treatment of herpes zoster. Probably the reason for not using one of them is the general belief that herpes zoster is due to a virus and it is well known that these drugs have no effect on virus diseases. The assumption that the disease is due to a virus may be wrong. Indeed it may turn out to be of streptococcal origin, and one bit of evidence for this is its quick response to sulfadiazine.

In the last five years I have treated eight cases of herpes zoster with sulfadiazine, the usual dosage being 1 gm. every three hours for twelve or fifteen doses. In all but one of these cases, pain and discomfort did not persist more than a few days. Inside of forty-eight hours the rash began to fade, turning from red to reddish brown, with disappearance of the vesicles, and in the course of a few weeks it disappeared altogether. All but one of these cases were seen early in the course, when there were comparatively few vesicles, which may account for their rapid response to treatment.

These cases are in marked contrast to a patient whom I treated before the sulfonamides were known. In this case the eruption extended in the course of a few days from the spinal cord to the sternum, covering the right, lower thoracic region. It was a solid bright red mass of papules and vesicles, about 7.5 cm. in width. The discomfort and pain were severe, requiring repeated doses of codeine and aspirin to control it. The patient was confined to her bed for nearly a month, with an elevation of temperature for the first two weeks. For six months after the rash subsided she complained bitterly of sharp, shooting pains in the right thoracic region, and even a year after the onset she still had occasional pain.

Since I have used sulfadiazine in these cases, I have seen nothing remotely resembling the severity of this case. After the rash has subsided, there have been no complaints or soreness in the area involved. In only one of the eight cases did the patient complain of pain after one week, and in this case, treatment was not begun until the rash was fully developed.

Most textbooks state that herpes zoster treated by orthodox methods ordinarily lasts from two to three weeks. My experience, prior to the use of sulfadiazine, leads me to believe that that prognosis is entirely too optimistic. The rash may last or disappear in two or three weeks, but the pain, which is the chief factor, may persist for weeks, months and even years. In my experience herpes zoster treated by orthodox methods is a prolonged, painful malady with an extremely uncertain prognosis.

AN IMPROVED GASTROSCOPE

To the Editor In spite of the well established usefulness of gastroscopy with the flexible gastroscope, there are still blind areas in the stomach that are relatively inaccessible. These have been partly overcome by the development in England of the Hermon Taylor flexible gastroscope, on the handle of which there is a racket that permits movement of the flexible portion after introduction into the stomach. This permits a much better view of the lesser curvature and anterior wall in the upper part of the body of the stomach. It also enables some increased visibility in the antrum. The slightly larger caliber of this instrument, making it a little more difficult to pass, is far outweighed by the better view obtained. In an occasional difficult case, one may have to revert to the original more flexible type of gastroscope.

I am now using the Hermon Taylor flexible gastroscope in every case, believing that the greatest advantages are, as claimed by the author, "abolition of blind areas in the stomach and the ability to move the objective about inside the stomach so as to inspect any particular area closely at will and to do so at more than one angle." The instrument is manufactured by the Genito-Urinary Manufacturing Company, Limited, 74 Devonshire Street, London W.1, England. After paying the U. S. Customs duty, the cost is approximately the same as that of American-made gastroscopes.

BOOK REVIEWS

Medicine in Industry. By Bernhard J Stern, Ph D. 8°, cloth, 209 pp. New York: The Commonwealth Fund, 1946. \$1.50. Studies of the New York Academy of Medicine, Committee on Medicine and the Changing Order.

In this monograph Dr. Stern discusses the social, economic, legal and professional aspects of industrial medicine. Data are presented on the rates of industrial disability and the limited extent of preventive services. He deals with recent developments in health and insurance programs, the problems of the handicapped and the relations between the industrial physician and the general practitioner. The work is well documented, with statistical tables and adequate lists of references to the various topics.

The first chapter is devoted to a well written short history of the subject dating from ancient times to the present. Then follow in order chapters on social and legislative backgrounds, the extent of industrial disability, the handicapped worker, preventive services, medical care and health insurance and the industrial physician. An appendix consists of a table showing industrial prepayment medical plans in operation in various industries in the United States and giving essential information concerning the plans. The book is well published and should be in all medical and public, as well as industrial, libraries and should prove valuable to all persons interested in the subject.

Eight Years of Public Health Work Jones County, Mississippi, 1937-1944. By Harry E. Handley, M D., and Carolina R. Randolph. 12°, paper, 80 pp. with 47 tables. New York: The Commonwealth Fund, 1946. 50 cents.

A continuous, well balanced program of county health work in Jones County, Mississippi, with emphasis on special problems, proved most effective during the period 1937-1944, during which almost \$300,000 was spent on public-health work. The county has an area of 706 square miles and the population was 49,227 at the time of the 1940 census. White persons comprised 72 per cent of the population, and 47 per cent were concentrated in two urban communities.

This report gives a detailed account of the work on sanitation, children under school age, school children and adults. The work on communicable diseases is emphasized. The Commonwealth Fund made substantial financial contributions to the basic budget of the health department in an effort to demonstrate that an adequate health service is worth while and deserving of local tax support. The local state and federal governments also contributed to the budget. The Commonwealth Fund is currently making contributions for new services in maternity care and immunization against whooping cough. The report contains a wealth of well organized and documented information.

The Diagnosis and Treatment of Pulmonary Tuberculosis. By Moses J. Stone, M D. and Paul Dufault, M D. With a foreword by Henry D. Chadwick, M D. 12°, cloth 325 pp., with 93 illustrations. Philadelphia: Lea and Febiger, 1946. \$3.50.

Although this manual is a continuation of the previous editions by John B. Hawes and Moses J. Stone, it is practically a new book since it has been almost entirely rewritten. The work is designed for medical students and general practitioners. The material is presented in a concise, well organized manner and is comprehensive in its scope. Emphasis is placed on radiologic diagnosis. Tracheobronchial tuberculosis and its operative treatment and artificial pneumothorax and thoracic surgery as means of treatment are discussed in special chapters. The text concludes with two chapters on tuberculosis in industry and on the social aspects of the disease. The first chapter is a short historical sketch of tuberculosis from 1500 B C. to the present time. Reading lists are appended to each chapter. The volume is well published and should prove valuable to all physicians interested in the disease.

Human Embryology. By Bradley M. Patten, M A., Ph D. 8°, cloth, 776 pp., with 446 illustrations. Philadelphia: Blakiston Company, 1946. \$7.00.

Embryology has within recent decades gone through a tremendous activity, especially in the field of its morphology—a morphology, it is true, that is not static but changing. The

more, the Foundation proposes to encourage medical research, especially that which has clinical application, and has established the award as one of its activities. Dr. Waksman receives the award for his original research in the field of antibiotics culminating with his discovery of streptomycin, which among its many uses gives promise of being of value in the successful treatment of tuberculosis.

Presentation of the \$5000 cash award will be made at a dinner to be attended by about a hundred outstanding medical men at the Ritz-Carlton Hotel, Atlantic City, on Thursday evening, June 12, during the week of the centennial meeting of the American Medical Association. Sir Howard Florey, of Oxford, England, who was knighted for his development of the clinical applications of penicillin, will make a brief address, following which the award will be presented to Dr. Waksman. Dr. Waksman's address will be entitled "Antibiotics and Tuberculosis — a Microbiological Approach."

NOTE

Dr. Robert P. Knight, at present chief-of-staff of the Menninger Clinic, Topeka, Kansas, has recently been appointed medical director of the Austen Riggs Foundation, Stockbridge, Massachusetts. Dr. Edgerton McC. Howard, who is now serving as acting medical director, will become associate medical director. Dr. Knight will assume his new duties on September 1.

CORRESPONDENCE

"THE LOST WEEK-END"

To the Editor: Hospitals today are badly overcrowded and have long waiting lists. Emergency surgical patients are readily admitted in most instances, a spare room or bed is usually reserved for just such a contingency or a temporary arrangement is made, such as placing the patient, even though of private status, in a ward. A medical emergency fares less satisfactorily, and patients who present no emergency but who are ailing and require the facilities of a hospital for diagnosis are placed on the waiting list and have a poor chance of being admitted for weeks or months.

The chief reasons for crowded hospitals appear to be the following: (1) The Blue Cross, the Blue Shield and other types of hospital and medical insurance, which permit benefits if the patient is hospitalized, (2) the widespread use of penicillin, which, to be given effectively, usually requires hospitalization, (3) the scarcity of trained nurses for home duty, (4) the shortage in the hospitals of nursing personnel and technicians, (5) the increased cost of operating hospitals in such a way that they function properly, and (6) the common custom of hospitals to run at low speed during week ends and holidays. The last reason is, in my opinion, an extremely important one. At such times the nursing and technical departments are manned by skeleton crews, which attempt to function only on an emergency basis. Out-patient departments are closed, although there is no doubt that if they were open not only would many be helped who would otherwise hesitate to seek help because of the fear of losing a day's work and pay but also advice would be given to others that might later forestall serious illness for which hospitalization and abstinence from work would become imperative.

As a direct result of the above factors patients are obliged to remain in the hospital, often at great expense to themselves or to industry, to wait their turn for the various special examinations ordered by the physician. A patient who enters the hospital Friday afternoon and who pays \$7 a day on the ward or \$10 or more a day for a private room, does not relish the knowledge that only emergency work will be done for him until Monday and that even some of the work that has to be done may not be reported till Tuesday.

Faced with this unprecedented demand for admissions, what steps have the hospitals taken? They have appealed for more nurses to keep their wards open, and they have raised salaries. It seems to me the one step not taken to increase their usefulness is to eliminate the week-end or holiday vacation. Were this latter step taken, an extra one and a half days would become available weekly for routine hospital diagnostic procedures. Thus approximately a week would be

gained monthly, or seventy-five days yearly, which, added to about eight days for holidays, would amount to nearly three months each year. In this manner, the capacity of the hospital, in so far as routine diagnostic procedures are concerned, would be increased by about a third.

How can the hospital provide for the full-time use of facilities? Obviously, it will be necessary to increase the personnel and to stagger the working hours. A further raise in salaries may be required. To provide for additional medical personnel, it might be possible to arrange for so-called "floaters." Thus, a private roentgenologist might be induced to "spell" his resident brother for a week end or for a specific number of hours each week. The same would be true of the pathologist, anesthetist and so forth. This problem would not differ materially from that of arranging for the summer vacation or for prolonged illness.

The money necessary to run the hospital on this full time schedule would become available from the increased income obtained by the more rapid turnover of patients. In addition, as the improved facilities and service offered by the hospital impressed the community, there would be a greater eagerness to contribute to its support.

PROFESSIONAL RESPONSIBILITY

To the Editor: In reference to Dr. Stratton's statement in the March 20 issue of the *Journal* regarding my recent experience with the Court, I wish to present to the fellows of the Massachusetts Medical Society the facts of the case.

On the morning of February 16, at about 2:00 a.m., I was called to see a young woman who had been criminally attacked. The car in which she and her escort were riding had been stopped by blocking the road, the door window smashed, her escort ordered out by two masked men at gun point, the girl taken out by a third man at gun point and then criminally attacked by the three men in turn.

I was fully satisfied that the girl's story was true, and examination showed unmistakable evidence of assault. Her family made it plain that they wished nothing said of the matter and refused to consult the police. I agreed that it was a private matter and that, so far as I was concerned, their wishes would be respected.

On my return home, however, and on reflection of the incident, I decided that, for the protection of the public, the police should be notified of the affair. That same morning I gave all the details, excepting names, to the police and informed them that I was doing this without the patient's knowledge and against the expressed wish of her family.

Two weeks later, a young man was killed when two gun men ordered him and his girl companion into the back seat of his car and took possession of the machine. The police then asked me for the identity of the young lady whom I had treated, on the supposition that this murder might have been committed by the same men who had assaulted her.

When permission was sought from the family for police questioning, they took the attitude that I had broken faith with them by reporting the incident. I told them that I had done so for the protection of the public and reminded them that I had not revealed the girl's identity and would not do so without their permission. They steadfastly refused to give the consent requested.

On my refusal to reveal the identity of the girl to the Grand Jury on professional grounds, I was jailed. The girl's family then came forward and arranged with the State Police for the questioning of the girl and her escort to effect my release.

I believe that it is unfortunate that, under existing Massachusetts statutes, a physician has only the Oath of Hippocrates as justification for keeping a pledge of privacy given to a victimized patient. I respectfully ask that the Committee on Legislation consider the desirability of effecting an amendment of the present law to grant to physicians the privilege that the public assumes we already possess and that is recognized by law in New York, Pennsylvania and many other states.

the parent and the school. In the long chapter entitled "In Search of Knowledge" various types of questions propounded by children are noted, and a pattern for answers is suggested by the author. The final chapter discusses the opposition to sex education and the need for such education. In the appendixes will be found a tentative scheme for education, specimen circulars to be sent to parents and specimen lectures on the subject. For reference purposes the absence of an index is to be deplored. This text should prove useful to all interested persons.

Medical Uses of Soap. A symposium. Edited by Morris Fubben, M.D. 8°, cloth, 195 pp. Philadelphia: J. B. Lippincott Company, 1946. \$3.00.

This second printing of a valuable monograph first published in 1945 has an additional chapter on the surgical uses of soap.

Endocrine Function of the Hypophysis. By Harry B. Friedgood, M.D., assistant clinical professor of medicine, University of Southern California School of Medicine, and senior attending physician, Los Angeles County Hospital. 8°, cloth, 211 pp., with 36 illustrations. New York: Oxford University Press, 1946. \$4.50. Reprinted from *Oxford Loose-Leaf Medicine*.

By reprinting this monograph the Oxford University Press makes it possible for interested physicians and small libraries to own this concise but comprehensive treatise without having to procure the complete *Oxford Medicine*. The work is divided into five parts. The first discusses anatomy, embryology and phylogeny of the hypophysis; the second, the cytophysiology and biochemistry of the adenohypophysis; the third, the biologic, biochemical, physiologic and genetic concepts of growth; the fourth, the chemical disorders of growth; and the fifth, the cytophysiology, biochemistry and pharmacology of the neurohypophysis. This monograph should be in all medical libraries and in the collections of all persons interested in the subject.

Principles of Hematology, with 106 Illustrative Cases. By Russell L. Haden, M.D., chief, Medical Division, Cleveland Clinic. Third edition, revised. 8°, cloth, 366 pp., with 173 original photomicrographs and 95 original charts and drawings. Philadelphia: Lea and Febiger, 1946. \$5.00.

This manual is written for the student and physician and not for the specialist, and emphasis is therefore placed on the fundamental principles of hematology. Highly technical procedures, such as the study of the Rh factor, are omitted. The type has been completely reset, and corrections have been made to bring the subject up to date, including a description of the technique of bone-marrow puncture and the study of bone marrow films. The book is well printed on good paper in a good type and is well illustrated.

Life House Physician. By Vice-Admiral Ross T. McInture, Surgeon General of the Navy. 8°, cloth, 244 pp., New York: Putnam's Sons, 1946.

Dr. McInture was the personal physician of President Roosevelt from the day of his first inauguration in 1933 until his death on April 12, 1945, and was also his companion, friend and confidant. He accompanied the President on his many journeys—to Newfoundland, where the Atlantic barrier was signed off the coast, Casablanca, Teheran, and Egypt.

He speaks with authority on the health and physical fitness of the President and of his struggle to overcome his infirmity due to infantile paralysis. He tells of the reasons behind his running for the presidency in 1940 and 1944. The volume is also an inside story of the political life of the presidential years. The text is written in an easy narrative style.

Courage and Devotion beyond the Call of Duty. Being a partial record of official citations to medical officers in the United States Armed Forces during World War II. Second preliminary edition, July, 1946. 12°, paper, 1024 pp. Evansville, Indiana: The Johnson and Company, 1946. Free.

The first issue (November, 1944) contained only 256 pages. The present text is divided into two parts, citations to in-

dividuals and citations to groups. Information is incomplete on a number of physicians and a few groups listed at the end of the volume, and the publisher invites corrections and additions and further information prior to issuing the final deluxe edition. This book is a valuable biographical reference source.

Manual of Applied Nutrition. A publication of the Dietary Department, Johns Hopkins Hospital. Second edition. 8°, paper, 103 pp. Baltimore: Johns Hopkins Hospital, 1946. \$1.50.

This manual has been revised and edited by a group representing several clinical departments and the Nutrition Committee of the Johns Hopkins Hospital. All available knowledge and experience have been used in its preparation, and although compiled for the use of a particular hospital, it should prove useful to clinicians and dietitians everywhere. It contains a wealth of material on all types of diets, general and special, given in terms of food constituents, as well as routines for special hospital services. There is a section on the feeding of infants and children. Other special material includes recommended normal dietary allowances for men, women and children, tables of normal measurements of males and females from birth to twenty years in relation to age and height, physiologic data concerning biologic body substances, food values of common substances, data for acid-base calculations, routine house diets and high-calorie diets. This text should prove valuable to medical librarians as a reference source.

Health Examinations. Prepared for the Medical Society of the County of New York by the Special Committee on Preventive Medicine. 8°, paper, 144 pp. Reprinted by Mead Johnson and Company, 1946. Free.

In this short manual a number of physicians discuss briefly the various topics relating to health examinations in young and old persons, from the newborn infant to persons over sixty-five years of age. Included are chapters on premarital and prenatal examinations, the emotional development of children from birth to the sixth year and from the sixth to the twelfth year, the psychology of adolescence and the emotional factors in senescence. Emphasis is placed on the healthy adult, especially between forty-five and sixty-five years of age. Special chapters are devoted to the ears, eyes, teeth and nutritional deficiency diseases. These outlines should prove useful to all physicians called on to make periodic health examinations.

A Memoir to the Academy of Sciences at Paris on a New Use of Sulphuric Ether. By W. T. G. Morton, of Boston in the U. S. A. Presented by M. Arago in the autumn of 1847. With a foreword by John F. Fulton, M.D. \$1.50. Historical Library, Yale Medical Library, Publication No. 14. 8°, paper, 24 pp. New York: Henry Schuman, 1946.

In this memoir, written by Morton in his twenty-eighth year, he gives the background of his discovery and the relations of his claims to those of Wells and Jackson. The appendix printed with the original French edition, but not reprinted in *Littell's Living Age*, is omitted in this reprint. The original memoir is rare, and this inexpensive edition should be welcomed by all persons interested in medical history and should be in all medical-history collections.

Notes on Nursing. What it is, and what it is not. By Florence Nightingale (London, 1859). 8°, cloth, 79 pp. Reprinted Philadelphia: J. B. Lippincott Company, 1946. \$1.25.

This reprint is an exact offset facsimile of the original printing of a classic in the field of nursing. It includes even the advertisements appended to the text. It is recommended for all libraries, medical, nursing and public, and this inexpensive edition makes the volume available to all nurses and others interested in the history of nursing.

Psychotherapy in General Medicine. By Geddes Smith, associate, The Commonwealth Fund. 8°, paper, 38 pp. New York: The Commonwealth Fund, 1946. 25 cents.

This pamphlet gives a detailed report of a postgraduate course in psychotherapy conducted in April, 1946, at the Center of Continuation Study, University of Minnesota.

subject has been handled mainly as a series of superimposed changes of architecture. One may say with reasonable certainty that it is now reasonably complete — just as gross morphology was quite definitely established seventy-five or ninety years ago.

For many years Dr. Patten has contributed heavily to the development of this science, and he is admirably suited, both by his knowledge and his genius for exposition, to writing this volume, which stands as an excellent and quite complete codification of the morphology of embryology.

It is well to have available such a well crystallized and understandable text of this aspect of embryology, for one may dare to assert that we stand on the threshold of a more comprehensive science of the embryo — a science in which successful attempts have already been made in physiology, chemistry and pathology.

A few examples may be chosen from divergent fields: the experiments in embryo mechanics, including the potency of isolated anlage and the presence of "organizers" of "energizers" developed in the writings of Spemann, Waddington and Weiss, the influence of the sexual hormones on both sexual and other development — for example, that of estrogen on bone growth (Bremer), the influence of transmitted defects of the glands of internal secretion on body build (Stockard), and the time of assumption of function by the various organs, such as the prenatal and postnatal maturation of the various parts of the nervous system (Conel).

A few problems of embryonic pathology have been explained: the transmission of congenital defects from "tainted" stock, the cause and prevention of erythroblastosis fetalis and the causation of congenital defects by rubella in the mother.

The aim of the comprehensive embryology of the future appears to be to make embryology now and in later times no longer merely a preclinical science but one of daily clinical application. It is necessary for the intelligent physician to familiarize himself with embryology. For him, as well as for the medical student, this work may be heartily recommended. It is authoritative and written lucidly and with much emphasis on application. The format is likewise excellent, with many fine drawings.

Group Psychotherapy: Theory and practice. By J. W. Klapman, M.D. 8°, cloth, 344 pp., with 14 illustrations. New York: Grune and Stratton, 1946. \$4.00.

The expression "so many and so few" may well be applied to the present situation regarding the mentally ill and the number of psychiatrists available. Group psychotherapy arose out of dire necessity and is still in the formative stage. This book is of value not only to sum up past and present knowledge in the field but also to point the way for the formulation of technique.

After a brief account of the development of group psychotherapy, the author traces its mental, moral and cultural origins. The developmental defects due to social isolation are emphasized, and the unique value of the demonstration of social standards and social conscience in group psychotherapy is indicated.

Methods used vary from the analytic school to the repressive, inspirational modes of psychotherapy. The personality of the therapist is of great importance. The action of numerous intragroup factors is described. Whenever possible, the procedure should be used in conjunction with individual psychotherapy.

Group psychotherapy is viewed as a method of affective re-education — "an adjustment of internal relations to external relations." For this purpose the lecture method and class and discussion periods are valuable. The psychodrama is used to "bring the patient to maturity by easy and gradual stages."

Other fields for group psychotherapy are in the outpatient clinic, for the treatment of problem children and their mothers and in private psychiatric practice.

Ancillaries to group psychotherapy are encouragement of hobbies and special interests, clubs, special radio programs, institutional publications and a public-relations program for mental hospitals.

The results are difficult to estimate. By means of a number of objective tests and evaluation by therapist and patient, they appear gratifying. Education by any method is a long-term project.

Oral Medicine. By Lester W. Burket, M.D., D.D.S. With a section "Oral Aspects of Aviation Medicine," by Major Alvin Goldhush, D.C., A.U.S. 8°, cloth, 674 pp., with 350 illustrations. Philadelphia: J. B. Lippincott Company, 1946. \$12.00.

In this volume the objective of correlating many of the diseases of the oral cavity with systemic disease has been successfully reached. The author, who is a physician and dentist studying oral disease in a well organized clinic, is especially fitted to evaluate and stress the diagnosis and treatment of the important and frequent diseases of the oral cavity.

Case records of the patient with oral disease should include a detailed history, with a description of the lesions and all the pertinent laboratory procedures that are used in the diagnosis of any pathologic process in the body. This the author has accomplished by a complete type of record used in the department of oral medicine.

Ten sections, which include all aspects of diseases of the oral cavity, as well as a regional diagnostic index, give a complete coverage of oral disease. Ten color plates with sixty subjects are especially useful in depicting some of the more frequent diseases of the tongue and buccal mucosa.

One criticism of the volume is the tendency to include discussions on many local and systemic diseases that are unrelated to oral disease. Reference to books on general medicine would serve as more practical guides to the dentist or dental student in rounding out his knowledge of the relation of constitutional and oral disease.

The book can be recommended as a textbook in oral medicine for the dental student and as a guide to the practicing dentist and physician in correlating lesions of the oral cavity and disease found elsewhere in the body.

Western Reserve University Centennial History of the School of Medicine. By Frederick C. Waite, A.M., Ph.D. 8°, cloth, 588 pp., with 15 illustrations and frontispiece. Cleveland: Western Reserve University Press, 1946. \$6.00.

This centennial volume records, after the pattern of the Chinese drama, the history of the School of Medicine of Western Reserve University as a series of episodes in a progressive educational institution in which the professors are the chief actors and the students are the audience. In so doing, it epitomizes the history of medical education prior to the foundation of Western Reserve in 1843. An account is also given of the three rival local medical colleges, of homeopathic medical education in Cleveland and of several local hospitals. The work thus becomes a history of all institutional medical education in Cleveland during its first hundred years. The volume is divided into five books — a prologue, "The First Half-Century," "Ancillary Events," "The Second Half-Century" and biographical material constituting an epilogue.

The author, well known as a medical historian for his work on Vermont Medical College, was a teacher at Western Reserve for over fifty years, having been appointed professor of histology and embryology in 1901. His volume, which is exceptionally well written and entertaining, is a valuable and scholarly contribution to the history of medical education in America.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Sex Education: A Guide for parents, teachers and youth leaders. By Cyril Bibby, M.A., M.Sc., F.L.S., education officer to the Central Council for Health Education, England. 8°, cloth, 311 pp. New York: Emerson Books, Incorporated, 1946. \$2.50.

This English book has been revised by the changing of words and phrases having different meanings in the United States and by the deletion of passages not of interest to American readers. Footnotes have been added explaining British conditions. The subject is discussed from the viewpoints of

THE SHATTUCK LECTURE

THE CLINICAL SIGNIFICANCE OF SOME PECULIARITIES OF THE CIRCULATION IN THE KIDNEYS, LIVER, LUNGS AND HEART*

WILLIAM DOCK, M.D.†

BROOKLYN, NEW YORK

REFLECTION on the functional significance of the valves in the veins and in the heart led Colombo and Cesalpino to postulate a circulatory system in place of the long-accepted tidal flow of blood from the liver and heart. These anatomic peculiarities of the vascular system were also emphasized by Harvey, who first gave a quantitative description of the motion of the blood, based on the structure of the human heart and on experiments on living animals. In the past three decades more progress has been made in the quantitative study of the circulation of the viscera of man and animals than had been achieved in the previous three centuries. Much of this advance has been made possible by new technical methods, but data of some interest have also been obtained by the injection or perfusion of human organs post mortem by means of a technic that was possible even in the days of Harvey, and decisive answers have been given by animal experiments of a relatively crude and simple nature. Both methods were used to obtain quantitative answers to the query, What is the need of this organ for blood and what is the capacity of its vascular bed?

The blood supply of an organ must meet its needs during maximal activity. In muscles, the heart and digestive glands such as the parotid gland and the pancreas the need for oxygen during activity is many times that under basal conditions. A complete description of the circulation of an organ, in health or disease, must include an estimate of the oxygen needs, basal and maximal, the capacity of the vascular bed and the volume flow under varying conditions. The rates of flow during life are of utmost interest, and in the kidneys, liver and

brain they can now be measured with some accuracy in unanesthetized men as well as in animals. The measurement of capacity for post-mortem flow will be most informative if it can be compared with rates of flow measured during life, just as all post-mortem studies in the past have been given significance by correlation with careful clinical observation.

THE KIDNEYS

The kidneys may well be described as the organs that "work while you sleep." Their blood flow and excretory work are maximal under basal conditions and during fever, but drop off during effort, falling to extremely low levels when the body is violently active or under such stresses as are imposed by shock or hemorrhage.^{1,2} One might say that the function and blood flow depend on how much blood can be spared from other tissues. This paradox of behavior was the first and most remarkable discovery made with the modern technics for measuring blood flow in the organs of an intact, unanesthetized animal or those of man.

Most observers agree that renal blood flow and oxygen uptake are not related to excretory activity, but their conclusions are based on experiments that did not evoke a wide range of variations in osmotic work. The rat can secrete urine with a 10 per cent urea content, and the osmotic work is then almost sixty times as great as that of the kidneys of a rat excreting dilute urine with only 0.1 per cent urea.³ The oxygen consumption of the kidneys is augmented only 22 per cent with this enormous increase in osmotic work, but the caloric equivalent of the extra oxygen used is five times as great as that of the extra osmotic work performed (Table 1). In other words, the efficiency with which this extra osmotic work can be handled by the kidneys is 20 per cent—a high level for any vital process. The efficiency of their work when excreting dilute

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 20, 1947.
†From the Department of Medicine, Long Island College of Medicine.
‡Professor of Medicine, Long Island College of Medicine; director of medical service, College Division, Kings County Hospital.

Twenty-five physicians attended the lectures and seminars for a period of two weeks. The course was given to ascertain whether the general practitioner could be educated at the postgraduate level to care for psychoneurotic patients encountered in his general practice. The immediate results were the recognition by both students and instructors of new possibilities in the general practice of medicine, a warm response by clinic patients to treatment and a conviction on the part of most of the students that their usefulness and morale as physicians had been strengthened.

Sir W Arbuthnot Lane, C.B., M.S., F.R.C.S. His life and work By W E Tanner, M.S., F.R.C.S. 8°, cloth, 192 pp., one portrait. Baltimore: Williams and Wilkins Company, 1946. \$4.50.

This life of an eminent British surgeon covers the whole of his professional career from his student days until he became surgeon to Guy's Hospital. The surgical achievements of a man notable for his work on fractures and abdominal surgery and his advocacy of colectomy are depicted by Mr Tanner throughout the text. One chapter is devoted to a trip to America in 1918 as a member of a committee to stimulate interest in the cause of the Allies. A complete bibliography of Lane's published writings comprising three hundred and forty-six titles, arranged by subjects and compiled by Mr G A R Winston, Will's Librarian of Guy's Hospital, is appended to the text. This biography is recommended for all medical-history collections.

Principles of Neurological Surgery By Loyal Davis, M.D., Ph.D., D.Sc. (hon.), professor of surgery and chairman of the Division of Surgery, Northwestern University School, Chicago. Third edition, thoroughly revised. 8°, cloth, 540 pp., with 192 illustrations. Philadelphia: Lea and Febiger, 1946. \$7.50.

This standard text, intended for the use of medical students and general practitioners, has been revised to include the knowledge gained by the author and others in World War II. The volume is well printed on good paper, and the material is well organized. The illustrations and plates are excellent. The book is recommended for all medical libraries.

Currents in Biochemical Research Edited by David E Green. 8°, cloth, 486 pp. New York: Interscience Publishers, 1946. \$5.00.

This collection of essays covers the whole field of biochemistry and is the joint endeavor of thirty collaborators who are specialists in their particular fields. The work is semipopular in character and written in simple language but on a scientific plane and without sacrifice of scholarship. The contributions emphasize the focal position of biochemical research in biology, chemistry and medicine. They invade the fields of organic, analytical and physical chemistry and encompass pharmacology, chemotherapy, public health, genetics, photosynthesis and agriculture. The contrast between the type used and the soft paper is not good and makes for difficult reading. The volume is recommended for all medical libraries for reference purposes.

Modern Drug Encyclopedia and Therapeutic Index Edited by Alexander B Gutman, Ph.D., M.D., assistant professor of medicine, Columbia University, College of Physicians and Surgeons, attending physician, Presbyterian Hospital, and associate attending physician, Vanderbilt Clinic, New York City. Third edition. 8°, cloth, 1157 pp. New York: York Publishing Company, Incorporated. \$10.00.

This new edition of a standard reference work has been completely rewritten and reset. Obsolete preparations have been deleted, new drugs and biologicals have been added and the arrangement of the material has been simplified. It is planned to keep the volume up to date by the issuance of supplements from time to time in which new preparations will be described. Comprehensive indexes of therapeutic uses and drugs arranged by manufacturers and distributors add greatly to the value of the work. A good general index concludes the volume. The material is well arranged and divided into pharmaceuticals, biologicals and allergens. The text is well printed and the type composition makes for easy use.

The volume is recommended for all medical libraries and should prove valuable to physicians and others.

Clinical Laboratory Diagnosis By Samuel A Levinson, M.D., Ph.D., director of laboratories, Research and Educational Hospitals, Chicago, and professor of pathology, University of Illinois College of Medicine, and Robert P MacFate, Ch.E., M.S., Ph.D., assistant director of laboratories, Research and Educational Hospitals, Chicago, and assistant professor of pathology, University of Illinois College of Medicine. Third edition, thoroughly revised. 8°, cloth, 971 pp., with 192 engravings and 15 plates. Philadelphia: Lea and Febiger, 1946. \$10.00.

This standard treatise has been brought up to date, and a few new methods have been added. The chemical methods have been critically revised, and all other laboratory procedures have been changed to conform to the latest methods. A new chapter on tropical medicine and new material on penicillin in the blood, acid phosphatase, the latest bone-marrow findings with ten new pictures of bone-marrow films, Diodrast and inulin clearance tests, anthocyanin and phenylpyruvic acid in urine have been added. The text is well printed with a good type on heavy paper. The work is recommended for reference purposes.

NOTICES

MASSACHUSETTS PHYSICIANS' ART ASSOCIATION

The first yearly exhibition of works of art by members of the Massachusetts Physicians' Art Association will be held on the fourth floor, Hotel Statler, Boston, throughout the meeting of the Massachusetts Medical Society, May 20 to 22.

MASSACHUSETTS MEDICO-LEGAL SOCIETY

The annual meeting of the Massachusetts Medico-Legal Society will be held in Parlor C, Hotel Statler, Boston, on Wednesday, May 21, at 2.45 p.m.

PROGRAM

The District Attorney and the Medical Examiner. Hon. George E. Thompson, district attorney, Middlesex County.

Business meeting
Refreshments

All medical examiners, whether or not members of the Massachusetts Medico-Legal Society, are cordially invited to attend.

NEW ENGLAND HEART ASSOCIATION

The annual Henry Jackson Lecture, under the auspices of the New England Heart Association, will be given by Professor John McMichael, of the Postgraduate Medical School, London, England, at 8.15 p.m. on Monday, May 26, at the Boston Medical Library. His subject will be "Heart Failure".

A short business meeting will precede the lecture. Interested physicians and medical students are cordially invited to attend.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY

The general oral and pathology examinations (Part II) for all candidates will be conducted at Pittsburgh, Pennsylvania, by the entire Board from Sunday, June 1, through Saturday, June 7, 1947. The Hotel William Penn in Pittsburgh will be the headquarters for the Board. Formal notice of the exact time of each examination will be sent to candidates several weeks in advance of the examination dates. Hotel reservations may be made by direct application to the Hotel William Penn.

Candidates in Military or Naval Service are requested to keep the Secretary's office informed of any change in address. Applications are now being received for the 1948 examinations. For further information and application blanks address Paul Titus, M.D., Secretary, 1015 Highland Building, Pittsburgh 6, Pennsylvania.

(Notices continued on page xiv)

usually compensatory to renal arteriosclerosis and therefore a "good thing." It is a disturbance of vasomotor tone, probably varying greatly in its origin in different patients, or even in the same patient at different times. What complex interplay exists between the kidneys and the vasomotor center can be dimly perceived and remains to be elucidated.

Studies on the kidneys in shock have cast a new light on the old experiments on renal hypertension. A decrease in blood flow to the kidneys, whether due to a clamp on the renal artery or to shock, leads to a remarkable series of events.⁸⁻¹⁰ The most startling and unique is a decrease in renal metabolism and oxygen use roughly proportional to the decrease in flow of blood in the kidneys. The kidneys not only work while we sleep but also sleep when we are struggling to maintain life. When the renal blood flow is 10 per cent of normal, renal oxygen use is only 10 per cent of normal, and the blood in the renal vein is no more depleted of oxygen than under basal conditions.⁸ When renal blood flow is arrested and later released, the vascular bed of the kidneys is not widely dilated, as it is in a limb or in other viscera after temporary complete ischemia. In the latter sites, the flow instantly rises to many times the basal rate when the artery is released, in the dog it takes nearly an hour for renal vasoconstriction to pass off and for blood flow and metabolism to return to normal after ten minutes of complete arterial block.¹¹

Renal vasoconstriction in dogs and in men occurs after hemorrhage or shock. In man, it takes place in heart failure, or even when an erect posture, with a resulting decrease in cardiac output, is assumed.¹² It also occurs whenever pain, fear or anxiety is suffered.¹ At the times when other tissues require a large part of the cardiac output, the kidneys reduce both their extravagant demand for blood and their use of oxygen. Thus, they accumulate no oxygen debt.

Tigstedt showed that the kidneys contained a heat-labile protein that acted as a vasoconstrictor. More recently, it has been demonstrated that renin is a protein-splitting enzyme, capable both of liberating a pressor amine from one of the globulins of the plasma and of inhibiting the oxygen uptake of isolated slices of renal cortex.¹³ In rabbits, even after repeated injections have exhausted its vasoconstrictor action, renin causes an intense diuresis of fluid with about the composition of plasma filtrate.¹⁴ In a word, it stops tubular reabsorption as effectively as cyanide. Shock apparently leads to the release, in the kidneys, of an inhibitor of renal metabolism that also causes renal vasoconstriction and may cause vasoconstriction generally.

It is worth emphasizing that anoxia has no such effect on the kidneys. When arterial oxygen saturation is low, the uptake of oxygen by the kidneys is normal and renal venous blood is profoundly un-

saturated, renal blood flow increases slightly.⁸ No hypertension follows arterial anoxia. The mechanism for reducing renal metabolism and causing vasoconstriction in the kidneys is set in play only by lowering of the renal arterial pressure or pulse pressure, or by raising of the interstitial pressure in the kidneys. Obviously, such a mechanism can be set off only by acting on a sensitive structure in the vascular bed of the kidneys.

An anatomic structure that might serve such a purpose had been noted in many mammalian kidneys by the histologists, just as the valves of the heart and veins were seen by many anatomists long before Colombo, Cesalpino and Harvey were aware of their functional significance. In this case it was Goormaghtigh,¹⁵ of Belgium, who suggested, in 1939, that the renal pressor mechanism was probably related to the peculiar cells in the afferent arteriole of each glomerulus and the plaque of closely crowded epithelial cells in the distal convolution at the point where it touched the glomerular hilus. This structure takes different forms in various species. It shows unusual cytoplasmic granules, mitotic figures and even hypertrophy in animals subjected to acute renal ischemia.¹⁻¹⁶ Changes in the juxtaglomerular tissue have also been noted after renal trauma and even after shock due to adrenalectomy.¹⁷ In 1943 hyperplasia of this tissue was noted in kidneys of men who had been in shock for several days before death,¹⁸ and photomicrographs were made of such changes in the material at the Army Medical Museum (Figs 1 and 2). Goormaghtigh¹⁹ reported this change in similar material seen in Europe. No such changes are seen in chronic renal hypertension of dogs or rabbits, or in human hypertension of long standing.

Renin may be detected in the blood in some cases of shock and of acute hypertension, but it is not found even in the renal venous blood in chronic hypertension.²⁰ This makes it probable that this renal mechanism was evolved in relation to shock and hemorrhage, which are common hazards of all mammals under natural conditions, but was revealed in the laboratory by throttling of the renal artery — a phenomenon that has no natural analogy in the pathology of rabbits and dogs. The pressor mechanism is perhaps less important than the inhibition of renal metabolism. This protects the kidneys even from many hours of ischemia, whereas muscles and other structures are seriously affected by shorter periods of arterial block, and the brain is destroyed by even a few minutes of ischemia. Dogs' kidneys completely recover from two hours of total ischemia, and in 50 per cent of animals even after four hours of arterial block.²¹

The relations of juxtaglomerular tissue and renin are not known, possibly, the arterioles release a substance that activates renin precursor in the cortical epithelium. Renin escaping from the epithelial part of the juxtaglomerular apparatus, the

urine is quite low — only 0.08 per cent, as compared with 3.8 per cent for their work at the heaviest load. The rise in efficiency as work increases explains why, in the usual experiments on dogs and men, no relation between work and oxygen use can be detected.

It is not possible to measure the heat value for all the secretory work of the kidneys. Only the minimal possible amount is given by a study of urea concentration, but this is probably a considerable fraction of the total work. In any event, the extra oxygen consumed by the kidneys after changing from a low-protein to a high-protein

fever-producing substances even in infinitesimal traces.

There have been several reports on perfusion of human kidneys with physiologic saline solution or with serum, but when the rate of Diodrast clearance was measured it became obvious that the flow calculated by aqueous perfusion was only 10 to 20 per cent of the blood flow during life. By making sure that the renal vessels had passed out of rigor, and perfusing with oil, to avoid edema formation, Cox and Dock⁹ obtained in kidneys of young men rates of perfusion comparable with the most rapid rates observed when Diodrast was excreted during

TABLE 1 *Relation of Renal Osmotic Work* to the Oxygen Needs of the Rat and Its Kidney*

SUBJECT	OXYGEN UPTAKE		HEAT EQUIVALENTS	
	BY ANIMAL	BY KIDNEY	FOR RENAL OXYGEN	FOR OSMOTIC WORK ON UREA
	cc/min	cc/min	cal/min	cal/min
Control animal	4.0	0.21	1.05	00.0009
Animal fed 74 per cent casein diet	5.6	(0.22)	(1.10)	(00.0036)
Animal excreting 10 per cent urea	4.1	0.26	1.30	00.0500

*Work forced by feeding of urea and restriction of water intake.

intake is too small to be detected.⁴ This change of diet leads to hypertrophy of the kidneys, and after certain types of renal injury a high-protein diet may seriously jeopardize their recovery.⁵ Such a diet supplies not only urea but also aromatic acids, which the kidneys actively secrete five times as effectively as they filter off and concentrate urea.¹ It may well be that these aromatic acids stimulate hypertrophy and the increase in blood flow noted in kidneys at the onset of hypertrophy.⁶

The oxygen used by the rat's kidneys secreting 10 per cent urea is only 0.2 cc per gram per minute. The human kidneys probably never take up more than 0.1 cc per gram per minute,⁷ which could be supplied by a flow of 2 cc of normal blood, leaving the renal venous blood still 70 per cent saturated with oxygen. The rates of excretion of Diodrast and aromatic acids by human kidneys prove that the basal flow must be at least 4 cc per gram per minute. During the reaction to a pyrogen, such as typhoid vaccine, given intravenously the flow is almost 10 cc per gram per minute, even though fever is prevented by premedication with amidopyrin.¹ On the other hand, no significant rise in renal blood flow occurs with arterial anoxia due to high altitude or to low oxygen content of the alveolar air.⁸ The renal blood flow, which is many times greater than that necessary to supply the oxygen used by the kidneys, varies with the need to excrete substances noxious to the body. It is noteworthy that phenolic compounds are eliminated five times as efficiently as urea, and that maximal renal flow is evoked by

fever. This gave us a method for determining with some accuracy the effect of disease on the capacity of the vascular bed in various organs.

This method was applied, in 1939, to the study of the vascular bed of the kidneys in hypertension. At that time most of the outstanding investigators of renal physiology and pathology had enthusiastically or tentatively accepted the thesis that nearly all hypertensive patients had significant renal arteriosclerosis, and the corollary that nearly all hypertension was due to renal vascular disease.

In chronic uremia, whether due to pyelitis, nephritis or severe vascular disease, the perfusion rates were found to be low — less than 10 per cent of normal. Even in the absence of hypertension or uremia there was a decrease in the vascular bed with advancing age. But in the kidneys of hypertensive patients dying of stroke, coronary disease, heart failure or some intercurrent illness we usually found perfusion rates equal to those of normotensive subjects, and often as high as those of normotensive persons of the same age.⁹ We concluded, as have those who later determined flow during reaction to pyrogen in hypertensive patients, that in most cases the hypertension precedes any organic renal lesion.

The renal blood flow measured during life shows great fluctuations in normal subjects and even greater ones in many hypertensive persons. The true capacity of the renal bed can perhaps be measured only post mortem. The clinical fact of greatest importance is that hypertension is not

technic revealed in normal livers a capacity for flow well above the rates measured subsequently by Brainer and his colleagues²⁵ in men under basal conditions, using a catheter in the hepatic vein and a constant infusion of bromsulfalein.

Although anatomic studies indicate that the hepatic arterioles and the portal venules enter the sinuses of the liver lobule separately, the rate of perfusion through the normal portal vein drops a

patient with acute alcoholism whose liver weighed 3820 gm. in whom no cirrhosis had developed. It was our impression that portal perfusion was usually normal in cases with much perlobular scarring but with little fatty change or necrosis of the parenchyma (Table 3).

The capacity for hepatic arterial inflow, when portal flow was established, reached 1100 cc per minute in young normal subjects, 500 in old normal

TABLE 2 *Oxygen Needs of Tissues in the Intestine*

SUBJECT	OXYGEN UPTAKE				
	BY ANIMAL	BY HIND QUARTERS	BY LIVER AND GASTRO- INTESTINAL TRACT	BY KIDNEY	BY HEART
	cc / min	cc / min	cc / min	cc / min	cc / min
Control animal	4.0	0.25	0.9	0.2	0.4

Hyperthyroid animal	6.0	0.0	1.4	(0.5)	0.6

third when pressure in the hepatic artery is raised from 0 to 100 mm. during a double perfusion with oil, with portal inflow at 20 mm. In the livers of patients with alcoholic cirrhosis the portal flow fell, on the average, 78 per cent when flow at 100 mm. was established in the hepatic artery. This phenomenon was least marked in the cirrhotics not associated with chronic alcoholism, in which portal flow per gram fell, on the average, only 21 per cent. In many cirrhotic livers, decreases in portal perfusibility were noted when arterial pressure was 0. The lowest portal flow in a normal liver from an aged subject was 850 cc per minute corrected to

subjects and in patients with nonalcoholic cirrhosis, and rose to 1600 cc per minute in those with alcoholic cirrhosis, averaging 1360 cc in the last group. This is interpreted as confirming Herrick's²⁷ report of deranged portal-hepatic arterial ratios in cirrhosis. This is presumably due to the development of numerous minute arteriovenous fistulas analogous to the spider angiomas in the skin. The increased arterial flow is also borne out by the x-ray films of hepatic arterial beds injected post mortem with radio-opaque jelly (Figs. 3 and 4). The hyperplastic bed, which is most striking in alcoholic patients, is unusual in the others. Further information comes

TABLE 3 *Estimated Capacity for Blood Flow in Human Livers (Based on Perfusion with Oil Post Mortem)*

CONDITION OF LIVER	WEIGHT OF LIVER kg.	BLOOD FLOW			TOTAL cc / min
		HEPATIC ARTERY* cc / min	PORTAL VEIN† cc / min	PORTAL VEIN‡ cc / min	
Normal	1.6	800	1400	1000	1800
Fatty	5	700	180	~80	620
Cirrhotic (alcoholic)	2.1	1360	1000	270	1630
Cirrhotic (nonalcoholic)	2.2	550	1100	500	1450

viscosity of blood, whereas in the cirrhotic liver with the poorest flow the rate was 480 cc. In two cirrhotic patients with enlarged livers the portal perfusibility was equal to the highest rate — 1700 cc per minute — in the liver of a normal young man. Loss of liver substance requiring a blood supply, scarring in portal areas and narrowing of sinuses by swelling of parenchyma may contribute to the decrease in portal perfusibility. The lowest perfusion rate, 180 cc per minute, was observed in a

from Dr. Roy Cohn,²⁸ who observed the portal pressure during laparotomy in 4 cases of advanced cirrhosis. On occlusion of the hepatic artery for a brief period, the portal pressure fell 21 to 29 per cent, or the equivalent of 7 to 11 cm. of water. During the operation, the systemic systolic arterial pressure was not over 80 in these desperately sick patients so that the effect of the hepatic arterial inflow was less than it would have been with normal levels of pressure. Even after occlusion of the

macula densa, may act on the glomerulus and cause efferent arteriolar constriction. The relation of this entire mechanism to chronic renal hypertension is obscure, for in the chronic disorder no circulating vasoconstrictor substance can be demonstrated. Increased vasoconstriction in chronic renal hypertension is certainly mediated through the central

diseased livers, and since no effect of such diets on renal metabolism has been demonstrated, the logical clinician would not reduce the protein intake in kidney disease. Experience has, of course, shown that in both hepatitis and cirrhosis a high-protein diet is beneficial, even though it makes the liver "work" harder. On the other hand, there is striking evidence that such a diet further injures kidneys in some species of animals with experimental nephritis, even though it does not appreciably increase the oxygen requirement of the kidneys.⁶

The blood flow of the liver in man is about 1 cc per gram per minute.²⁵ This supply comes from two sources, the portal vein, with a pressure equivalent to 10 to 20 mm of mercury, and the hepatic artery, with a pressure of 100 mm or higher. In man all the portal flow may be diverted into the inferior vena cava without damage to the liver, and

FIGURE 1 *The Glomerulus and Juxtaglomerular Tissue of a Normal Man Who Met a Sudden Death from Accident*

The macula densa (X-X) is a closely packed group of epithelial cells on the side of the distal convoluted tubule that touches the hilus of the glomerulus. The arteriolar cells, above and to the left of the lines, are shown by the arrow.

nervous system, but by humoral and not by reflex stimulation of the vasomotor center.²²⁻²⁴ When one recalls that minute quantities of pyrogen alter the "set" of the heat-regulating center, it is easy to believe that minute quantities of a substance from abnormal kidneys may alter the "set" of the vasomotor center.

THE LIVER

A kidney is the most marvelous anatomic structure in the body, its complexities being more awe inspiring than the thigh joints, which Solomon described as the "work of the hands of a cunning workman." The liver, on the contrary, is one of the simplest glandular structures in the body. Its oxygen uptake is determined by its metabolic activity, and in the rat rises from less than 0.1 cc per gram per minute on a protein-free diet to more than twice that amount on a diet with a 74 per cent protein content.⁴ The specific dynamic action of protein, or the rise in total metabolism after a protein meal, is due almost entirely to this intense hepatic activity (Table 2). The clinician, accustomed to prescribing rest for ailing men or organs, would predict that high-protein diets, by adding to metabolic activity, would retard recovery of

FIGURE 2 *Findings in the Kidney of a Man Who Lived for Five Days, in Severe Shock, after Injury*

The long, unusually cellular macula densa (X-X-X), and the large mass of cells in the arteriolar wall (arrow), are characteristic.

in dogs ligation of the hepatic artery causes no apparent damage. Such ligation may have serious effects on the liver in a patient with chronic biliary-tract disease. Arterial lesions are rare in the liver, as contrasted with the heart or kidney of man, and chief interest in the vascular bed of the liver is aroused by the severe vascular derangement seen in cirrhosis.

Few have questioned the relation between portal hypertension, with splenomegaly, esophageal varices and ascites, and a reduction in the portal bed by scar tissue. But no proof of such a reduction in portal bed had been offered, when, in 1941, the livers were perfused with oil post mortem.²⁶ This

mental pneumothorax³². They found that less than a fifth of the cardiac output went through the collapsed lung, and thus ended a controversy, based on indirect and conflicting evidence, that had lasted thirty years. They also utilized the procedure to demonstrate the increased cardiac output occurring with experimental arteriovenous fistulas³³. A flood of papers on the use of this method immediately followed, by 1930 Baumann had used the technic of ventricular puncture in man, and in 1941 Cournand and his co-workers began the catheterization of the right side of the heart that has opened a new chapter in the measurement of blood flow through the lungs in health and disease. By simultaneous measurement of right ventricular pressure the resistance offered by the pulmonary vascular bed can be measured. So far, no one has collected data, based on perfusion with oil post mortem, on the effect of varying degrees of collapse, distention and pulmonic pressure on the capacity of the vascular bed of the lungs of subjects of different ages and with various pulmonary lesions.

Although it is difficult to obtain quantitative data on collateral between the pulmonic and bronchial circulations by double perfusion, it has been possible to learn much by injection with radio-opaque or deeply colored jellies. Wood and his associates³⁴ in the Department of Pathology at Stanford University demonstrated extensive hyperplasia of the bronchial arterial bed and anastomosis with the pulmonary system in ulcerative tuberculosis, bronchiectasis and lung abscess, and in bronchogenic but not in metastatic cancer. At Cornell, anastomoses were demonstrated between the pulmonic and bronchial veins in normal adults, as well as extensive hyperplasia and varices in the submucous plexus of bronchial veins in cases of mitral stenosis³⁵. This established the source for the brisk hemoptysis that occurs in these patients with no evidence of infarction or intense pulmonary congestion.

Because the lungs occupy a large space and the blood circulates through them at a relatively low pressure, posture greatly alters the flow and the quantity of blood in the apex and base or in the dorsal and ventral parts. Posture also alters the volume flow of blood through the lung. On reclining, the blood that fills the veins below the diaphragm is no longer held back by gravity, and the effective venous pressure, the quantity of blood in the lungs and the output of the heart are increased, the last by as much as 30 per cent in some subjects.

The venous blood in the lungs must return to the left ventricle, which has its center of mass near the ventral chest surface and the diaphragm, slightly to the left of the midline. Because of the effect of gravity on this flow, venous pressure at the bases, expressed in its equivalent of water, is 20 to 30 cm. greater than that at the apex of subjects in the orthopneic position. When the patient is in the right semirecumbent posture, frequent with cardiac

patients, the venous pressure in the lateral and basal parts of the right lung is 10 to 20 cm. higher than that in any part of the left lung. These simple facts are of paramount importance in explaining the frequency of basal pulmonary edema and of right-sided hydrothorax in cases of cardiac failure, since the formation of tissue fluid increases rapidly with the rise in venous pressure³⁶.

The flow of lymph also increases with the rise in venous pressure and the dilution of toxic substances and the removal of bacteria or dusts such as silica, is most rapid and effective at the base of the lungs. At the apex, not only is the venous pressure low but also the arterial inflow is compromised when adults are sitting or standing. The systolic pressure in the right ventricle is 18 to 30 in recumbent subjects³⁷. It is perhaps only 12 to 25 when the patient is sitting, and the column of blood from the ventricle to the upper part of the lungs then exerts a pressure equally great. There is always a fall in pressure along the course of the arteries, and this must be more marked on the right side because the right pulmonary artery arises at an acute angle from the direction of flow in the pulmonic conus and pursues a tortuous path around the aorta. Consequently, the apical fourth of the left lung and the apical third of the right can have practically no blood flow for two thirds of each day in the life of sedentary people. Silica, coal dust, bacteria and toxins cannot be removed effectively when lymph flow ceases. Antibodies formed by the body or antibiotics given parenterally will not reach this zone. Oxygen tension will be high because aeration continues and the unsaturated blood from the systemic veins is not pumped up by the right ventricle. All this creates ideal conditions for tubercle bacilli, and it is not remarkable that in this region tuberculosis flourishes even when, in spite of positive findings in the sputum and constant seeding to all parts of the lung, no progressive lesion appears at the bases for many years^{38, 39}.

Although it is impossible to determine the relative significance of high venous pressures at the base and low arterial inflow at the apex in altering the resistance to tuberculosis, it is noteworthy that in rabbits and in cattle progressive lesions of tuberculosis are most numerous at a site anatomically opposite from the apex — namely, the dorsal and juxtadiaphragmatic part of the lower lobe^{40, 41}. Here, too, arterial inflow is reduced and venous pressure greatly lowered, since this portion of the lungs is highest above the heart in four-footed beasts. The high incidence of tuberculosis in cases of congenital pulmonary stenosis, which greatly lowers pulmonic arterial pressure, and the low incidence of active tuberculosis in mitral stenosis, with pulmonic pressure two to six times normal,³⁷ strongly support the thesis that arterial inflow is of crucial importance. The effect of gravity on the lungs thus explains the remarkable efficacy of rest

hepatic artery, however, the portal pressure did not fall to normal in any of these cases, so that arteriovenous fistulas were not the main cause of portal hypertension

I have seen only 2 cases of Banti's disease accompanied by portal hypertension without portal or splenic thromboses and with histologically normal

FIGURE 3 *Hepatic Arterial Bed, after Lead-Gelatin Injection, in the Normal Liver, as Visualized by X-rays*

livers. The only conceivable explanation is a congenital defect in the communications of the portal and hepatic arteries, with telangiectasia in the lobules. This could be determined during life by the fall of portal pressure to normal on occlusion of the hepatic artery, and post mortem by double perfusion or even by hepatic arterial injection. So far, no such studies have been reported.

To what extent hepatic arterial flow is increased in chronic portal hypertension in various types of cirrhosis can best be determined by observations made during operations to provide portocaval anastomosis. When such arteriovenous fistulas are important factors, a complete portocaval shunt is obviously preferable to one between the splenic and the renal vein, for the latter does not close off the leak between the artery and the portal vein. It is to be hoped that surgeons will soon provide data on the fall of portal pressure with arterial occlusion in various types of liver disease, and especially in the Banti syndrome. In this connection one recalls the following comment of Sir Thomas Lewis²⁹

Surgeons, if they would, could contribute heavily to clinical science. The special opportunities for observation presenting themselves during the progress of operations may be noted, they are not utilized as they might be. Such investigations must remain purely incidental, and must always be conducted within strictly prudent bounds.

Another anomaly of the hepatic circulation that occurs in dogs — but not in cats, rodents, herbivora or man — is worth notice, since it has led to some interesting confusion in pharmacologic study. The dog has a muscular sphincter at the outlet of the hepatic vein, and spasm of this sphincter, evoked by histamine³⁰ and to a lesser degree by digitalis,³¹ leads to a pooling of blood in the liver and portal bed, a fall in the systemic venous pressure and a marked reduction in cardiac output. Digitalis causes a fall of venous pressure and cardiac output in normal men, but the decrease is much less striking than that in dogs. In describing the hepatic element in the dog's response to digitalis, Tainter

FIGURE 4 *Hepatic Arterial Bed from a Chronic Alcoholic Patient with Portal Cirrhosis. Note the extensive hyperplasia*

and Dock³¹ took pains to point out that no such action could be postulated as contributing to the effect of digitalis in cardiac failure in man.

THE LUNGS

The blood flow through the lungs was the first to be measured. In 1870 Fick pointed out that by division of the oxygen uptake or carbon dioxide output by the difference in gas content of blood from the right and left sides of the heart the flow through the lungs could be determined. This was actually done, in dogs, sixteen years later by Gréhant and Quinquaud and in horses during exercise, rest and digestion by Zuntz.

Up to 1923 this technic had not been used in North America, nor had it been employed to study the effects of disease. In that year two house officers at the Peter Bent Brigham Hospital used this method to measure the blood flow through the collapsed lung and the opposite lung in experi-

mental pneumothorax³². They found that less than a fifth of the cardiac output went through the collapsed lung, and thus ended a controversy, based on indirect and conflicting evidence, that had lasted thirty years. They also utilized the procedure to demonstrate the increased cardiac output occurring with experimental arteriovenous fistulas³³. A flood of papers on the use of this method immediately followed, by 1930 Baumann had used the technic of ventricular puncture in man, and in 1941 Cournand and his co-workers began the catheterization of the right side of the heart that has opened a new chapter in the measurement of blood flow through the lungs in health and disease. By simultaneous measurement of right ventricular pressure the resistance offered by the pulmonary vascular bed can be measured. So far, no one has collected data, based on perfusion with oil post mortem, on the effect of varying degrees of collapse, distention and pulmonic pressure on the capacity of the vascular bed of the lungs of subjects of different ages and with various pulmonary lesions.

Although it is difficult to obtain quantitative data on collateral between the pulmonic and bronchial circulations by double perfusion, it has been possible to learn much by injection with radio-opaque or deeply colored jellies. Wood and his associates³⁴ in the Department of Pathology at Stanford University demonstrated extensive hyperplasia of the bronchial arterial bed and anastomosis with the pulmonary system in ulcerative tuberculosis, bronchiectasis and lung abscess, and in bronchogenic but not in metastatic cancer. At Cornell, anastomoses were demonstrated between the pulmonic and bronchial veins in normal adults, as well as extensive hyperplasia and varices in the submucous plexus of bronchial veins in cases of mitral stenosis³⁵. This established the source for the brisk hemoptysis that occurs in these patients with no evidence of infarction or intense pulmonary congestion.

Because the lungs occupy a large space and the blood circulates through them at a relatively low pressure, posture greatly alters the flow and the quantity of blood in the apex and base or in the dorsal and ventral parts. Posture also alters the volume flow of blood through the lung. On reclining, the blood that fills the veins below the diaphragm is no longer held back by gravity, and the effective venous pressure, the quantity of blood in the lungs and the output of the heart are increased, the last by as much as 30 per cent in some subjects.

The venous blood in the lungs must return to the left ventricle, which has its center of mass near the ventral chest surface and the diaphragm, slightly to the left of the midline. Because of the effect of gravity on this flow, venous pressure at the bases, expressed in its equivalent of water, is 20 to 30 cm greater than that at the apex of subjects in the orthopneic position. When the patient is in the right semirecumbent posture, frequent with cardiac

patients, the venous pressure in the lateral and basal parts of the right lung is 10 to 20 cm higher than that in any part of the left lung. These simple facts are of paramount importance in explaining the frequency of basal pulmonary edema and of right-sided hydrothorax in cases of cardiac failure, since the formation of tissue fluid increases rapidly with the rise in venous pressure³⁶.

The flow of lymph also increases with the rise in venous pressure, and the dilution of toxic substances and the removal of bacteria or dusts, such as silica, is most rapid and effective at the base of the lungs. At the apex, not only is the venous pressure low but also the arterial inflow is compromised when adults are sitting or standing. The systolic pressure in the right ventricle is 18 to 30 in recumbent subjects³⁷. It is perhaps only 12 to 25 when the patient is sitting, and the column of blood from the ventricle to the upper part of the lungs then exerts a pressure equally great. There is always a fall in pressure along the course of the arteries, and this must be more marked on the right side because the right pulmonary artery arises at an acute angle from the direction of flow in the pulmonic conus and pursues a tortuous path around the aorta. Consequently, the apical fourth of the left lung and the apical third of the right can have practically no blood flow for two thirds of each day in the life of sedentary people. Silica, coal dust, bacteria and toxins cannot be removed effectively when lymph flow ceases. Antibodies formed by the body or antibiotics given parenterally will not reach this zone. Oxygen tension will be high because aeration continues and the unsaturated blood from the systemic veins is not pumped up by the right ventricle. All this creates ideal conditions for tubercle bacilli, and it is not remarkable that in this region tuberculosis flourishes even when, in spite of positive findings in the sputum and constant seeding to all parts of the lung, no progressive lesion appears at the bases for many years^{38, 39}.

Although it is impossible to determine the relative significance of high venous pressures at the base and low arterial inflow at the apex in altering the resistance to tuberculosis, it is noteworthy that in rabbits and in cattle progressive lesions of tuberculosis are most numerous at a site anatomically opposite from the apex—namely, the dorsal and juxtadiaphragmatic part of the lower lobe^{40, 41}. Here, too, arterial inflow is reduced and venous pressure greatly lowered, since this portion of the lungs is highest above the heart in four-footed beasts. The high incidence of tuberculosis in cases of congenital pulmonary stenosis, which greatly lowers pulmonic arterial pressure, and the low incidence of active tuberculosis in mitral stenosis, with pulmonic pressure two to six times normal,³⁷ strongly support the thesis that arterial inflow is of crucial importance. The effect of gravity on the lungs thus explains the remarkable efficacy of rest

flat in bed in the treatment of apical tuberculosis, as contrasted with miliary or other types of the disease. It should be noted that antibiotics will be least effective in reaching apical lesions when patients are allowed to sit up most of the day, so that the type of management introduced by Joseph Pratt will continue to be of value even after effective chemotherapy for tuberculosis has been developed.

The peculiar relations of the pulmonary circulation to the gravitational pull are of great practical effect in the management of both congestive failure and pulmonary tuberculosis—the two most frequent natural causes of death between childhood and senescence. In heart failure the orthopneic posture makes life tolerable, in apical tuberculosis it may make recovery impossible.

THE HEART

The oxygen requirements of the isolated hearts of rats, dogs and other mammals have been measured, as have the coronary flows in several species and in the human heart revived after death. In the rat, the oxygen used by the heart even in the hyperthyroid state with pulse rates over 300 is not over 0.6 cc per gram per minute.⁴² The oxygen used by the human heart probably never exceeds 0.1 cc per gram per minute and is believed to be about 0.06 cc during vigorous activity. That quantity can be supplied by a blood flow of 1 cc per minute, which leaves the venous blood still half saturated with oxygen. This maintains an oxygen tension adequate to allow diffusion of oxygen into the center of a muscle fiber twice the diameter of those in a greatly hypertrophied heart.

Cardiac hypertrophy is a mechanism of great adaptability. In arterial hypertension of gradual evolution the wall of the left ventricle becomes thicker, but the diastolic capacity does not increase, the fibers are thicker but no longer than normal.⁴³ But when increased output must be maintained, as in hyperthyroidism, anemia or valvular disease, the fibers grow longer, and the chamber becomes more capacious. Loss of efficiency, the usual cause of heart failure, leads to an increase in both length and thickness of the fibers. Hypertrophy occurs rapidly, and when the stimulus is removed the muscle returns quickly to its normal weight.⁴⁴ One of the problems of great importance to the cardiologist is whether the coronary bed adapts itself to the growth of the myocardium with the same nicety as the muscle fibers adapt themselves to the load imposed on them. Several authors have suggested that congestive failure occurred because hypertrophy outstripped the growth of the coronary bed. Kountz,⁴⁵ perfusing revived human hearts, observed control rates of flow up to 3 cc per gram per minute under vasodilator drugs. He found the rates low in hearts revived after death from cardiac

failure, but in such hearts only low perfusion pressures could be maintained.

The perfusion of hearts with oil has yielded decisive data, and in this case the data so far have not been supplemented even by the wielders of the vascular catheters. There has, of course, never been any doubt that occlusion or severe narrowing of the large coronary arteries that lie in the epicardium must reduce the flow to the heart muscle. The only perfusion rates below 0.7 cc per gram per minute, calculated as blood flow at the equivalent of 100 mm of mercury, were observed in hearts with severe coronary atherosclerosis, the lowest rate, 0.2 cc per minute, was in a heart with two large arteries occluded and constricted regions in most epicardial branches. In hypertrophy without coronary disease the flow rates were more than adequate to provide oxygen in excess of the needs of the thickest fibers.⁴⁶

As hearts grow from infancy to maturity the coronary perfusibility per gram of tissue decreases. After maturity, the average perfusibility of heart of normal weight decreases. The flow at ages sixty-six to eighty-five was 30 per cent less than that at ages twenty-five to forty. In hypertrophied hearts the flow per gram also decreases, but this appears merely as a smooth extension of the curve of the decline in the normally growing heart up to maturity. Even in the largest hearts of old men, where the main branches were patent the flow at 100 mm never fell below 0.7 cc per gram per minute. At the patient's usual diastolic pressure, the calculated flow fell below that level in only 2 cases of aortic insufficiency. Neither in the heart with the lowest calculated flow—0.45 cc at the patient's diastolic pressure—nor in any of the others had there been angina during life or fatty change in the myocardium post mortem.⁴⁶ These are the classic symptomatic and anatomic sequelae of cardiac anoxia, whether due to coronary disease or severe anemia.

Anatomic studies had given an equivocal answer to the question of coronary flow in cardiac hypertrophy. Injection of the arteries by Schlesinger's technic demonstrates a striking hyperplasia of the visible arteries, whereas capillary counts show no reduction in loops per fiber, and a decrease in capillary loops per gram of muscle.⁴⁷ It should be recalled that resistance to flow decreases as the fourth power of the radius of the vessel increases. Thus a 10 per cent increase in diameter of the minute vessels would cause an increase of nearly 50 per cent in flow, a 19 per cent increase would double it. Changes in caliber unperceived by the anatomist may greatly alter the perfusibility of an organ such as the heart, and the only real test of perfusibility is perfusion.

Perfusion shows that the possible flow in the heart of a healthy young man may be as much as 500 cc per minute, whereas in the hearts of older patients with hypertension the ventricles, two or three times

heavier, have possible rates of flow of 700 to 1000 cc. The coronary bed adapts itself to the needs of the organ it serves, as would be expected from the development of the vasculature in other sites — around the coarcted aorta, in the pregnant uterus and even in tumors. Having seen the intercostal arteries, many centimeters away from the tissue that needed blood, so dilated as a result of coarctation that the ribs themselves became eroded,⁴⁸ one would be surprised if the arteries in the myocardium could not hypertrophy to provide blood needed by hypertrophied muscle or by a region supplied by an occluded coronary branch.

The coronary bed is peculiarly liable to atherosclerosis, at least in populations with dietaries such as ours. Nearly a fifth of the sedentary men of North America die because of the vulnerability of the epicardial branches of the coronary system. Even in manual workers and elderly women the death rate from coronary disease is high. Occlusion may occur when the aorta and the rest of the arteries are in faultless condition, particularly in men under the age of fifty.⁴⁹

Even at birth these arteries have intimal layers thicker than those of any other vessels of similar size in the body, and this natural intimal thickness increases throughout life even if atherosclerosis fails to occur. In a small series, male infants were found to have far more striking intimal cushions than females.⁵⁰ Perhaps the earlier onset of disease and far higher mortality in males is due to this anatomic peculiarity. Men also drink more milk and eat more eggs than women, but the frequency of gallstones in women in North America makes it unlikely that the sex difference is due to lower blood cholesterol levels. In the Orient coronary disease and cholesterol stones are rare; there, men have more gallstones (of the calcium bilirubinate type) than women do.⁵¹ It may be concluded that atherosclerosis will occur in people with meat and dairy products in the regular diet, its predilection for the coronary arteries, in men and in certain families, may be due to an anatomic anomaly present at birth.

Using the oil perfusion technic and also glass microspheres of various sizes, Prinzmetal and his co-workers⁵²⁻⁵⁴ have studied the volume of collateral flow and the caliber of the cross channels in the heart. This has given further evidence of the adaptability of the coronary circulation under the stresses imposed by disease. Because of this adaptability normal cardiac function may be maintained for years after the occlusion of the largest arteries in the heart.

* * *

This description of the circulatory peculiarities of some of the viscera has emphasized the phases of investigation with which I am most familiar. The introduction of the vascular catheter and the use

of radioactive isotopes have opened up a vast program of study of the circulation in various organs of normal and of diseased men, and the description of this problem will be greatly modified in the next decade. Yet it is instructive to see that much can still be learned by the use of simple methods of post-mortem study and animal experiment.

Perfusion with oil serves to measure the capacity for flow through many organs. Perhaps the most urgent problem connected with the study of aging is the disseminated cortical atrophy that is associated with loss of memory, originality and judgment. Methods for measuring the cerebral flow during life are now being perfected, but by perfusion it is possible to measure flow through each major subdivision of the cerebral vascular bed and to correlate changes with the histology of the brain and with clinical observations on cerebration and total cerebral flow. It is to be hoped that this method will be applied in all clinics where blood flow is being measured during life. In most such centers post-mortem material from patients who have been subjected to elaborate quantitative studies is being examined exactly as it might have been in the days of Virchow or Rokitsanski.

During the last year of a life largely devoted to bettering the care of the sick and the education of physicians, George Cheyne Shattuck made a generous gift for the purpose of improving the teaching of morbid anatomy at Harvard. This eminent practitioner from his own experience and from the work of such contemporaries as Bright and Addison, fully realized the supreme value of complete post-mortem examination correlated with well planned clinical study. New methods for clinical study merely make more essential the evolution of a morbid anatomy adequate to maintain this effective correlation. Even with the use of methods available to all for the past seventy years, it is possible for pathologists and even practitioners to make essential contributions to an understanding of the diseases that remain the "captains of the men of death."

DWARFISM IN HEALTHY CHILDREN ITS POSSIBLE RELATION TO EMOTIONAL, NUTRITIONAL AND ENDOCRINE DISTURBANCES*

NATHAN B. TALBOT, M.D.,† EDNA H. SOBEL, M.D.,‡ BERTHA S. BURKE, M.A.,§ ERICH LINDEMANN, M.D.,¶ AND SHIRLEY B. KAUFMAN, M.S. ||

BOSTON

CHILDREN in good health who are receiving an adequate diet tend to follow a relatively standard pattern of growth and maturation. Although moderate deviations from the average trend are commonly considered to be normal physiologic vari-

intestinal, renal, hepatic, skeletal or endocrinologic system. There remained, however, a group of 28 boys and 23 girls, two and a half to fifteen years of age, in whom no such abnormality could be found. The present paper is the result of attempts to dis-

FIGURE 1 Heights of Various Types of Dwarfed Children

Results are expressed as height age divided by chronological age times 100 (ordinate) and are plotted against approximate chronological age (abscissa). A height-age ratio of 100 indicates that the subject is of average normal height for the age and sex. The shaded area gives the approximate range of normal.

ations, extreme deviations suggest that some abnormality exists. In the past few years more than 100 abnormally short children have been encountered in the pediatric clinics of this hospital. In approximately 50 per cent of these patients the stunted growth could be related to a definite disturbance in the pulmonary, cardiovascular, gastro-

cover and eradicate the cause of stunted growth in such patients.

Description of Patients

Figure 1 presents the data on the stature of these patients and gives comparative information on the height of patients dwarfed as the result of authentic hypopituitarism,¹⁻¹¹ hypothyroidism¹² and Cushing's syndrome¹²⁻¹⁶ respectively. A number of the so-called "pituitary dwarfs" of the literature are also represented.¹⁶⁻²⁵ The results are expressed in terms of height age times 100 divided by actual age, the height age of each subject being the average age of normal children of the same height and sex.²⁶ None of the patients under discussion had a height age that was more than 80 per cent of the actual age. Expressed in another manner, all the present subjects were 5 cm. or more shorter than 90 per cent of

normal children of the same sex and age. It can also be seen that the patients were approximately as short as those with authentic endocrine dwarfism and that they were no taller than most of the so-called "pituitary dwarfs" of the literature.

Information on the stature of the parents and siblings of these patients may be of interest. Data on

FIGURE 2 *Weight Relative to Height of Various Types of Dwarfed Children*

Results are expressed as weight divided by height age times 100 (ordinate) and plotted against height age (abscissa). The upper clear area (A) includes patients considered to be overweight for their height, the shaded area (B) suggests that the weight is within normal limits for height, the lower clear area (C) includes patients who are underweight for height. The circled points represent children with Cushing's syndrome who were not dwarfed³⁰ and so emphasize the fact that there is a tendency to be overweight in this condition.

the height of the parents were available in 39 of 51 cases. In 74 per cent the father was reported to be more than 158 cm and the mother more than 152 cm tall. Nineteen patients had younger siblings, 84 per cent of whom were as tall as or taller than the patients. In only 5 per cent of cases were there close relatives whose stature was reported to be remarkably short. This information appeared to provide little justification for the assumption that the small stature of the children was necessarily due to hereditary limitation of growth capacity.

Figure 2 gives information concerning the weight of these patients. To relate their weight to their height, the results are presented as weight age

times 100 divided by height age. A ratio of 85 to 115 is considered to be approximately within normal limits (Fig 2, Group B). Higher ratios suggest that the subject is overweight (Fig 2, Group A), whereas lower ratios suggest that he is underweight (Fig 2, Group C) for his height. The values presented indicate that about 70 per cent of the patients in the series belonged to Group B, the remaining 30 per cent were underweight (Group C). In contrast, the patients with authentic endocrine dwarfism tended to be of at least average normal weight for height (a weight-age ratio of more than 100), and about half—those in Group A—were overweight (a ratio of more than 115) according to this definition.

The weight of a child relative to his height is not always an adequate index of the subcutaneous fat stores.^{31, 32} Thus, although there was a tendency for the patients who were relatively more underweight to be thin, clinical examination indicated that all but 3 of the children whose weight was within normal limits for height also tended to have scanty subcutaneous tissue stores (Fig 3).

Figure 4 presents information concerning the skeletal maturation of the various types of patients. The skeletal age was estimated from roentgenograms of the hand and wrist according to Todd's standards. The results are expressed in the following ratio: skeletal age times 100 divided by actual age. It is evident that the skeletal age of the majority of the patients was retarded behind the actual age to approximately the same degree as the height age. In this respect the patients did not differ consistently from the authentic endocrine or the so-called "pituitary dwarfs." There was, however, a tendency for the hypothyroid children to show the greatest and those in the present series and the so-called "hypopituitary patients" the least degrees of retardation in skeletal maturation.

Nutritional History

Since it did not seem appropriate to explain the small stature of these patients a priori by a hereditary limitation in growth capacity and because no physical diseases could be discovered, the average daily food intake of 29 patients was evaluated by means of detailed dietary histories obtained through procedures described elsewhere.³³ The results are considered below from two points of view: the average daily caloric intake and the average intake of certain building materials—namely, protein and calcium. Generally speaking the nutritional histories of the majority of these children indicated clearly that they were difficult feeding problems and had been so for the major portion of their lives, in many cases since infancy.

Caloric intake. Figures 5 and 6 present values for the estimated average caloric intake of each of the girls and boys on whom nutritional histories were obtained. In these figures the continuous curves

running upward from left to right represent the average caloric intake of normal children of corresponding ages, whereas the interrupted curves stand for a standard deviation below the average and approximate the lower limit of normal for this community.^{21, 22} It can be seen that the caloric intake of 85 per cent of the patients was at or below the lower limit of normal for chronologic age. These

Protein intake Figure 7 sets forth estimations of the average daily protein intake in the cases in which nutritional histories were obtained. The continuous curve running upward from left to right represents the protein allowances for boys recommended by the Food and Nutrition Board of the National Research Council, the same curve gives the recommended allowances for girls up to eleven years,

FIGURE 3 Physical Appearance of Various Types of Dwarfed Children

Patient A, aged six and a half years, was underweight for her height (Group C, Fig. 2) and was very thin. Patient B, aged thirteen and a half years, was an extremely thin member of Group B (weight within theoretical normal limits for height). Patient C, aged twelve and a half years, was of normal weight for his height (Group B) and appeared to be adequately nourished. Patient D, aged eleven years old, was overweight for his height (Group A) and was moderately obese. Patient E, aged twelve years and an example of authentic hypopituitarism, was a member of Group A and was moderately obese.

data, however, do not take into consideration the influence of subnormal size on caloric requirements. Presumably, the requirements should be scaled down somewhat to correct for the fact that these patients had a smaller protoplasmic mass and surface area than normal children of the same age. On the other hand, the caloric requirements may easily have been greater than those of normal children of the same size or height to enable them to catch up to normal and to meet the larger caloric requirements for activity reported for older children.²⁶ When such variables as these are considered, it seems reasonable that the trends shown in Figures 5 and 6 are valid. Certainly, they are in keeping with the clinical observation that the majority of the children had poor subcutaneous fat stores.

whereas the interrupted line at the right indicates allowances for older girls. The values were lower on the average than the allowance for age recommended by the National Research Council. When calculated in relation to body weight, however, the average daily intake of protein of these patients was 2.2 gm per kilogram of body weight, with a range of 1.5 to 3.6 gm. There was essentially no difference between the average daily values found for children of normal weight (Group B, 2.1 gm per kilogram of body weight) and those for underweight subjects (Group C, 2.4 gm).

There is evidence that children can grow — that is, they can be in positive nitrogen balance — when the daily intake of protein is as little as 0.7 gm per kilogram of body weight.²⁷ In this connection it is

of interest that the daily increase in body protein during the major part of childhood amounts to only

FIGURE 4 Skeletal Development of Various Types of Dwarfed Children.

The results are expressed as skeletal age divided by chronologic age times 100 (ordinate) plotted against chronologic age (abscissa). The vertical lines in each section indicate the range of height ages divided by chronologic ages times 100 shown in Figure 1. The interrupted horizontal line indicates where the bone age (and height age) plots would fall if they corresponded to the average normal for sex and age.

about 0.1 gm per kilogram of body weight.¹² Viewed in this light, a daily protein intake of ap-

FIGURE 5 Average Total Daily Caloric Intake for Girls (ordinate) Plotted against Chronologic Age (abscissa).

The squares stand for children of normal weight for their height (Group B, Fig. 2), and the triangles represent children who were underweight for their height (Group C, Fig. 2). The numbers adjacent to these symbols are case numbers. The continuous curve running upward from left to right gives the approximate average normal total caloric intake for children of corresponding age and sex. The lower interrupted curve is one standard deviation below the average normal and gives the approximate lower limit of normal. These normal data for children one to nine years of age are based on data of Beal, Burke and Stuart¹⁴; the data for children older than nine years are National Research Council daily allowances modified to fit the fact that girls have their maximum growth spurt and hence caloric requirements at thirteen years, whereas boys have theirs at about fifteen years.

proximately 2 gm per kilogram of body weight is apparently in excess of minimum growth requirements.

Evaluation of the adequacy of the protein intake, however, also demands simultaneous consideration of the caloric intake. The primary nutritional re-

FIGURE 6 Average Total Daily Caloric Intake for Boys Plotted against Chronologic Age.

The legend of Figure 5 explains the chart.

quirement of the body is for calories to meet the energy requirement. When the caloric balance becomes negative, there is an increased tendency for

FIGURE 7 Average Total Daily Protein Intake for Boys and Girls Plotted against Chronologic Age.

The continuous curve running upward from left to right gives approximately the allowance recommended by the National Research Council for boys. The same curve gives values for girls up to eleven years, and the interrupted line at the right-hand end of the continuous curve gives values for older girls.

dietary protein to be used for fuel rather than for growth. Thus, a protein intake that is ample for growth under conditions of caloric adequacy may be

insufficient under conditions of caloric inadequacy. Consequently, it seems probable that in our patients, the protein intake per se was not incompatible with growth, but that it may have been rendered inadequate by the poor caloric intake.

Calcium intake Calcium as a limiting dietary factor was also considered. In 18 of the 29 subjects the intake of this mineral was more than the daily minimum requirement of 600 to 800 mg for children of preschool age.³³ The remaining 11 patients were found to be taking 200 to 600 mg daily. It should

intake of the 11 children receiving a total of 600 mg or less per day was 22 mg per kilogram of body weight — the range being 10 to 35 mg. It is of interest that growing children habituated to a low-calorie diet can store in their bodies as much as 89 per cent of a small calcium intake — 200 to 250 mg per day.⁴⁰ These facts suggest that a small child receiving 200 mg of calcium per day can absorb and retain 175 mg, which exceeds normal growth requirements for such a child. Although it is difficult to draw more than tentative conclusions from such

FIGURE 8. Changes in Body Weight and Nitrogen Balance Induced by Variations in Caloric Intake in a Thin, Underweight Dwarfed Child (Patient A, Fig 3)

In the upper portion of the chart, the caloric intake per kilogram per day is indicated by hollow circles connected by an interrupted line. The black circles connected by a solid line represent body-weight measurements. In the lower portion of the chart are set forth nitrogen-balance data. The distance from the baseline to the double horizontal line gives the nitrogen intake. The cross-hatched area adjacent to the baseline gives the nitrogen output in the stool, and the vertically lined area above this gives the output in the urine. The balance is indicated by the distance between the intake and the urine plus stool output.

be mentioned that the recommended allowance for calcium increases with age through the peak of the adolescent growth spurt and that these children ranged in chronologic age between two and fifteen years. It may also be stated that the minimum allowances referred to above were recommended for subjects whose stores were already saturated. It has been calculated that the daily calcium growth of normal children amounts to between about 5 and 7.5 mg per kilogram of body weight.³⁹ Expressed in terms of total retention per day, this amounts to approximately 68 mg in normal four-year-old subjects and increases to a maximum of 190 mg in normal sixteen-year-old children. The average daily

observations, the foregoing information indicates that few, if any, of the patients had a calcium intake that was incompatible with normal growth. This was supported by the fact that neither x-ray films of the wrist nor determinations of serum calcium, phosphorus and alkaline phosphatase values showed changes suggestive of rickets.

Again, relating the calcium intake to the protein intake, or more properly to the nitrogen balance, is pertinent. Bone growth occurs as the result of protein matrix formation. Secondly, calcium salts are deposited in the matrix. Consequently, when skeletal protein anabolism is limited, the amount of calcium that can be deposited is necessarily limited.

Effect of Calories on Nitrogen Balance

The foregoing nutritional studies thus suggested that caloric deficiency was the cause of the retarded growth in certain patients. To investigate further the possible significance of this idea, one of the underweight and apparently calorically undernourished children of Group C was admitted to the Metabolic Ward of the Massachusetts General Hos-

FIGURE 9 Growth in Height and Gain in Weight of Same Patient before and after Hospital Admission When Dietary Intake Was Increased

Results are expressed as height age (black circles connected by solid line) and weight age (white circles connected by interrupted line) plotted according to the scale on the ordinate against chronological age (abscissa). One measurement of skeletal age is represented (X). The diagonal dashed line indicates where the height, weight and skeletal age symbols should fall if the patient were average normal for her age and sex.

pital for a study of the relation of variations in caloric and in protein intake to the growth rate as measured by the nitrogen balance. The techniques used were similar to those reported elsewhere.⁴¹ The appearance of this child at the time of admission is presented in Figure 3A. Figure 8 sets forth the chief metabolic observations. During Period A the patient received a diet calculated to yield approximately 1200 calories and 48 gm of protein a day. On this regime she gained weight at the rate of about 35 gm and retained nitrogen at the rate of about 0.6 gm daily. During Period B the patient received the same protein intake, but the daily content of the diet was reduced to 1000 calories. On this diet the patient lost body weight and showed a less positive nitrogen balance (about 0.4 gm per day). Finally, in Period C the intake was restored

to a level of 1200 calories, but the daily protein intake was reduced to 25 gm, or 1.9 gm per kilogram of body weight. On this diet she gained weight at a rate of 30 gm and stored nitrogen at the increased and rapid rate of 0.7 gm a day. Not shown in the figure are numerous measurements of the basal metabolic rate and of the rate of insensible weight loss. Neither of these measurements gave grossly abnormal values, and neither showed any striking changes during the course of these periods.

These observations suggest that in this child the caloric intake was a more important determinant of the rate of growth (protein anabolism as reflected by the nitrogen balance) than the protein intake. They further confirm the thesis that a daily protein intake of approximately 2 gm per kilogram of body weight is sufficient to permit rapid nitrogen storage, for the anabolism of 0.7 gm of nitrogen per day should yield approximately 7 kg of true muscle in a year.⁴² The other implication of these findings — namely, that this child should grow rapidly in stature if continuously provided with an adequate diet — is borne out by the measurements recorded in Figure 9. It is seen that whereas the patient had grown and gained exceedingly slowly during the years prior to these studies, she gained and grew extremely fast during the succeeding months, in the course of which she ate much more food.

Viewed as a whole, therefore, these clinical, nutritional and metabolic studies coupled with data in the literature¹⁸ suggest that the retarded growth of the thin patients of the present series was due primarily to caloric malnutrition. Because the calories were inadequate, it may be that the body tended to adapt itself by using protein for energy rather than growth. This is discussed below.

Psychiatric and Social Studies

The possibility that some of these children were calorically undernourished led to attempts by the nutritionists and medical staff to improve the diet of thin patients in Groups B and C. These efforts met with little success, often because the children could not be interested in the idea of eating more food. In 4 of 21 cases this lack of interest could be attributed to moderately marked mental deficiency (Fig 10). On the other hand, no explanation was provided by the information obtained in the other 17. Accordingly, these patients were studied from the social-service and psychiatric points of view. For control purposes 7 dwarfed but apparently well nourished patients were likewise studied (Fig 10).

As indicated in the figure, the patients fell into six groups. In Group I nothing remarkable was found. As mentioned above, the children of Group II were found to be moderately mentally deficient as evidenced by an intelligence quotient of about 70. Group III was made up of patients from families whose economic resources were markedly limited and in which the mother's intellectual equipment

was not sufficient to enable her to carry through adequate housekeeping and nutritional management of the child. In Group IV it was found that for emotional reasons the mother was unable to accept and perform her nurturing functions with the child. Some of these mothers had not wanted the pregnancy and had emotionally rejected the child after birth. In others adjustment to womanhood in general and motherhood in particular was poor. In still others poor marital adjustment and hos-

similar studies on run-of-the-mill hospital patients are not yet at hand. The need for such studies is clearly evident. Nevertheless, the available information suggests strongly that the thin dwarfs were undernourished either because of anorexia due to emotional disturbances or mental deficiency or because of a combination of such disturbances and poverty and ignorance on the part of the parents.

Although the period of follow-up study has been too short to warrant any detailed evaluation of

7 WELL NOURISHED DWARFS

21 THIN DWARFS

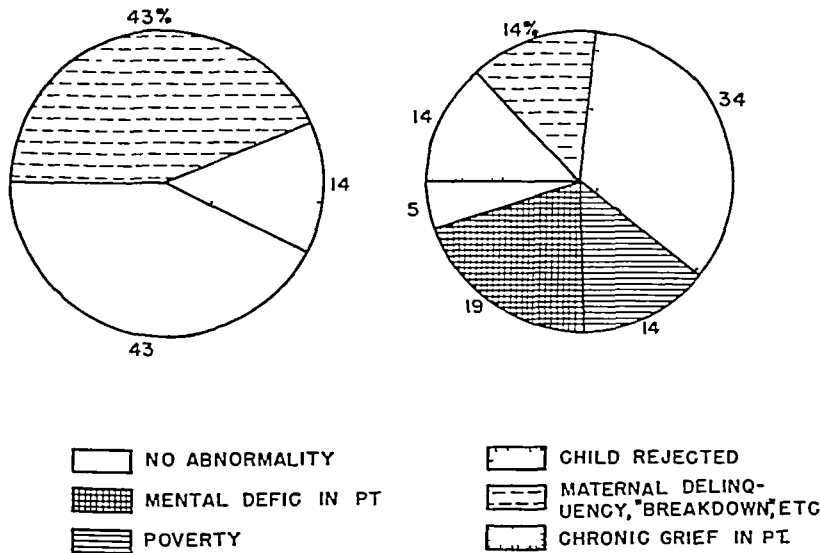

FIGURE 10 Incidence of Mental Deficiency, Poverty and Various Emotional Disturbances in 21 Thin Dwarfs Compared with that in 7 Well Nourished Dwarfs

tility to the husband led to hostile attitudes toward the child. In Group V, because of a "nervous breakdown" or delinquency on the part of the mother, the home situation was as seriously disturbed as in the preceding group. One mother was in jail because of indecent conduct. Another had had a psychotic reaction in the puerperium. The others had reactive depressions making them profoundly preoccupied with their own concerns and inaccessible to the children. The children of Group VI all had severe emotional reactions, with chronic grief* and anorexia due to a broken home brought about by death, divorce or desertion.

It will be noted that the incidence of social or psychiatric difficulties was remarkably high in the thin dwarfs. The control group of apparently well nourished dwarfs was too small to permit any clear analysis. The incidence of difficulties, however, was lower in the control subjects. Unfortunately,

psychiatric therapy, it can be said that such therapy has already been followed by a major improvement in appetite in 3 children of Groups B and C. After the change in appetite these children have shown a decided increase in the rate of weight gain and subsequently in the rates of growth and maturation. The patient presented in Figures 8 and 9 is an example. The prognosis for such successful psychotherapy is probably fair to good in about half the children studied to date.

The Role of Growth Hormone

There is evidence that during the major part of childhood, growth in stature (protoplasmic anabolism) is dependent not only on the assimilation and transportation of building materials (protein, minerals and so forth) to the growing end organs but also on the presence of the pituitary growth hormone.¹² Growth defined as an increase in stature due to the construction of new skeletal (proto-

*This type of reaction has been described elsewhere by one of us (E. L. W.)

plasmic) tissue proceeds exceedingly slowly in the absence of this hormone, even when the dietary intake is more than sufficient to meet the requirements for maintenance and growth. Under these circumstances the protein ingested is catabolized, and any surplus calories are stored as body fat. Contrariwise, provided there is an intake of building materials in excess of minimum maintenance requirements, growth can proceed under the influence of growth hormone even if the total caloric

intake is insufficient to meet the total energy requirements¹². Under such circumstances any caloric deficit is made up by the combustion of body fat. According to these ideas it may be postulated that children such as the present patients in this series, who were ingesting every day 2 gm of protein per kilogram of body weight, should have grown at a satisfactory rate had they been producing appropriate amounts of pituitary growth hormone. In other words, the slow growth of these children may have been due, in the final analysis, to a relative deficiency of pituitary growth hormone. Although it was impossible to test this theory by the administration of a potent preparation of pituitary growth hormone, it was possible to give the substitute pro-

FIGURE 11 Effect of Oral Methyl Testosterone Therapy on Growth Rates of 8 Dwarfed Children

Four of these children were well nourished, and 4 of them were thin. The rates of growth before treatment were observed over a period of at least six months. The rates of growth during treatment indicate the rates found during the first approximately three months after therapy was begun. The position of the symbols for each child relative to the abscissa indicates roughly the age of the patient at the time when therapy was started. The numbers beside the symbols are case numbers. The shaded area depicts the approximate normal limits of growth increments expressed, like the results, as centimeters per three months.

intake is insufficient to meet the total energy requirements¹². Under such circumstances any caloric deficit is made up by the combustion of body fat.

According to these ideas it may be postulated that children such as the present patients in this series, who were ingesting every day 2 gm of protein per kilogram of body weight, should have grown at a satisfactory rate had they been producing appropriate amounts of pituitary growth hormone. In other words, the slow growth of these children may have been due, in the final analysis, to a relative deficiency of pituitary growth hormone. Although it was impossible to test this theory by the administration of a potent preparation of pituitary growth hormone, it was possible to give the substitute pro-

tein anabolic agent — methyl testosterone* — to 4 thin patients of the present series, as well as to 4 similarly dwarfed but well nourished children. Following a control period of several months these patients were given 20 to 30 mg of the drug by mouth daily for a period of about three months. The data in Figure 11 show that all were growing at an abnormally slow rate during the control period. During the period of therapy, on the other hand, there was universally a striking increase in growth rate

to normal or superior levels. These observations indicate that the thin as well as the well nourished dwarfs were capable of normal growth rates. To the best of our knowledge this change in rate was not accompanied by important changes in appetite. The observations may also be interpreted as suggesting again that the ultimate cause of the abnormally slow growth during the control period was a relative deficiency of the naturally produced pituitary growth hormone.

Such a thesis is well supported by the evidence in the literature. It is known that malnutrition secondary to famine or to anorexia nervosa is accompanied by a tendency to amenorrhea, asper-

*Kindly supplied by Schering Corporation, Bloomfield, New Jersey.

matogenesis, retarded sexual maturation and the like.⁴⁴⁻⁴⁷ These changes in all probability signify that the organism tends to adapt itself to nutritional privation by becoming relatively hypopituitary

Recovery from Malnutrition Accompanied by Failure to Resume Normal Growth

These thoughts have a practical bearing on the problem presented by the few dwarfed but relatively heavier and apparently well nourished patients of the present series. The medical and nutritional histories obtained on some of these children suggested strongly that they had undergone a period of nutritional privation in earlier childhood. It is conceivable that such children adapted themselves to the malnutrition by a diminution in pituitary activity but failed to resume normal pituitary function when the diet improved. Patient C in

nourished. Unfortunately, no early records of his weight are available. The first records of height (Fig. 12), however, show that he had grown very little between the ages of six and nine years. At about the eighth year he was adopted into another home, where he promptly gained much weight. Figure 12 shows that although he continued to gain in weight from the ninth to the thirteenth year, he failed to accomplish a corresponding increase in

FIGURE 12 Observations on the Growth in Height, Gain in Weight and Skeletal Maturation and 17-Ketosteroid Output of a Dwarfed Boy (Patient C, Fig. 3)

This boy was eventually treated intermittently for a period of two years with 20 to 30 mg of methyl testosterone daily by mouth. The form of this chart is similar to that of Figure 10

Figure 3, as well as Figures 12 and 13, illustrates this possibility

This patient was said to have been normal up to the age of four years. At that time his mother died, with the result that for approximately four years he had to shift for himself in the daytime while his father was away at work. During this period he is reported to have subsisted largely on coffee and doughnuts. When eight years of age he was found by a relative to be small and poorly

FIGURE 13 Detailed Record of Increments in Height of Same Patient before, during (speckled areas) and After Periods of Methyl Testosterone Treatment

stature. Physical examination at the age of thirteen years revealed an apparently healthy, intelligent and well nourished, but abnormally small boy. There were no evidences of sex maturation. Ordinary clinical laboratory tests, as well as roentgenograms of the skull, disclosed nothing of note. The bone age was retarded four years. The urinary 17-ketosteroid output was likewise below normal limits.

In view of the fact that the nutrition seemed to be adequate, no attempt was made to stimulate growth by dietary therapy. Since the dwarfism, together with the retarded skeletal maturation and lowered urinary ketosteroid values, suggested a lack of normal pituitary activity, the patient was treated intermittently with the substitute growth hormone, methyl testosterone, over a period of two years. This was given by mouth in daily doses of between 20 and 30 mg. Figure 12 reveals that this therapy promptly induced a marked acceleration in growth rate. There was a corresponding increase in the rates of weight gain and skeletal maturation. The urinary 17-ketosteroid output also tended to rise from abnormally low to normal levels during periods of methyl testosterone therapy. Figure 13 gives more detailed information and shows again that prior to this medication, the growth rate was exceedingly slow. During the first period on methyl testos-

terone, the rate of growth increased markedly, but returned to essentially pretreatment levels when the drug was discontinued. This deceleration of growth indicated that the first growth spurt was not spontaneous. A similar response occurred during the second course of therapy, but this time there was no decline in growth rate when the drug was stopped. The administration of the drug for the third and final time had no appreciable effect on the rate of growth. From this time on the patient continued to show satisfactory progress in growth, weight gain, skeletal and sexual maturation and urinary ketosteroid excretion. These observations suggest strongly that he had in fact been suffering from a functional type of hypopituitarism and that during the therapy he resumed normal pituitary function.

A similar progress in growth was noted in 4 other patients of Group B following one or two courses of methyl testosterone of three months' duration. It is tempting to postulate, therefore, that testosterone not only directly stimulates protoplasmic anabolism but also promotes increased pituitary activity. This contention is supported by the changes in urinary 17-ketosteroid output observed in the patient described above. Methyl testosterone is not per se metabolized and excreted as a urinary 17-ketosteroid.⁴⁸ Therefore, the increase in ketosteroid output noted during periods of methyl testosterone therapy presumably reflects an increase in the rate of production of 17-ketosteroid precursors by the glands that normally produce them — namely, the adrenal cortices or testes, or both. Since the activities of the glands are controlled by the anterior portion of the pituitary body, the rise in ketosteroid output appears to signify that an increase in pituitary activity had taken place. It is entirely possible that a similar increase in pituitary activity would have occurred spontaneously at a later date.

Mention should probably be made of the alternative possibility that malnutrition or emotional disturbances, or both, induced an overproduction of anti-growth hormones by the adrenal cortex — the "S" hormone of Albright.³⁰ This seems relatively unlikely. Consideration of other explanations for the retarded growth of the patients seems inappropriate at present. The purposes of this paper will have been fulfilled if the problems presented by physically normal, dwarfed children gain wider attention.

SUMMARY

A sizable number of physically sound but abnormally small children were investigated. It was noted that some were grossly underweight for their height and that the great majority appeared to have scanty subcutaneous fat stores. Nutritional studies revealed that although the intake of building materials such as protein was probably adequate for growth, the total caloric intake appeared to be undesirably low. In the majority of cases this pre-

dominantly caloric malnutrition appeared to be related to anorexia—secondary to emotional disturbances. In 3 cases correction of emotional difficulties resulted in an improvement in appetite that was followed, in turn, by a rapid gain in weight and an appreciable increase in the rates of growth and maturation.

A few children failed to resume normal growth when the dietary inadequacies had been corrected. Furthermore, it was found that the growth rate of both poorly nourished and well nourished dwarfs could be increased markedly by the administration of a protein anabolic or growth hormone — namely, methyl testosterone — without any evident change in diet. In a few well nourished dwarfs growth continued spontaneously at a satisfactory rate after one or two short courses of testosterone therapy. These observations coupled with the evidence of the literature concerning the value of anabolic hormones and especially of the pituitary growth hormone as determinants of growth rate during childhood⁴⁹ suggested that the dwarfism in this group of children was due to a functional hypopituitarism occasioned by the limited caloric intake. If this thesis is correct, it may be assumed that this hypopituitarism reflected a homeostatic or adaptive reaction to the malnutrition.

The use of testosterone as initial treatment for the stunted growth of nutritional dwarfs seems illogical, correction of emotional and nutritional inadequacies commands first attention. On the other hand, when correction of these factors fails to accelerate growth and when the possibility of hypothyroidism has been ruled out, the daily oral administration of about 20 mg of methyl testosterone for one or two short periods may, especially in retarded boys of adolescent age, be followed by an acceleration in spontaneous growth and maturation processes. It cannot yet be said that such hormonal therapy is free from permanently harmful effects on testicular function.

A CLINICAL SYNDROME SIMULATING POLIOMYELITIS

RICHARD H. YOUNG, M.D.*

OMAHA, NEBRASKA

DURING the week August 11 to 18, 1946, a total of 34 new cases of poliomyelitis were reported in Nebraska, 176 cases having been reported for that year. With serious epidemics in the neighboring States of Minnesota, South Dakota and Colorado, there was considerable apprehension on the part of the people of this area. On the front page each day the press reported the new cases and the precautions to be taken. In letters to editors, readers asked for a spraying of the City with DDT, and offered new epidemiologic theories. The terror that past generations manifested toward "the plague" was displayed toward poliomyelitis. Precautions dictated by fears were at times extreme, particularly in this year, when transmission by contact and carriers had been stressed. In this situation of social anxiety, it was not remarkable that evidence of neurotic behavior was found.

During the week when 34 new cases of poliomyelitis appeared in the State, 5 cases closely simulating poliomyelitis were observed in private practice, in 4 of which the patients had hysterical paralysis of one or more extremities. These cases are presented below because of a similarity in the situational and psychologic mechanisms involved.

It is believed that an elucidation of the clinical features of these cases may serve to accent the importance of anxiety and other emotional factors in suspected cases of poliomyelitis. These cases also illustrate the value of determining the nature of the paralysis, for purposes of diagnosis as well as for treatment.

CASE REPORTS

CASE 1 L B, a 25-year-old housewife, was referred because of the development of a headache, chiefly occipital, stiffness of the neck and weakness in the left arm.

A nephew who had been living with the patient's family on a farm had developed poliomyelitis 5 days previously and had been sent to Lincoln, Nebraska, for hospital treatment. This experience had been disturbing to the patient and to the neighbors of the surrounding countryside, one of whom, in declining to pay her a visit, stated that she would be glad to come to the patient's home after the first frost.

Examination revealed the cranial nerves to be normal, except for some difficulty in moving the head from side to side, which was attributed to muscle stiffness. There was no particular stiffness in flexion of the head on the neck. The motor status showed the left arm to be held in a position of flexion and to be weak and limited in movements, but increased in muscle tone. The left leg also showed a minor degree of diffusely distributed weakness. The deep reflexes were equal and active. Superficial reflexes were present and normal in type. Sensory status revealed a left hemihypalgesia.

At the time of admission the patient had a temperature of 99.4°F and after the examination the nature of her illness had been explained to her, she was considerably relieved. She

was given 0.4 gm of sodium amytal (6 gr) that night, and on the next morning, with encouragement, she showed a full range of motor power and was allowed to return home.

CASE 2 G H, a 33-year-old housewife, was seen as an outpatient at the Lutheran Hospital because of backache and weakness of the left leg. Her physician reported a temperature of 99.6°F.

The patient stated that in 1939 her daughter had developed poliomyelitis, which had seemed to appear suddenly, the first awareness of the disease being when she fell out of a chair during an illness that had been considered to be influenza. For the previous day the patient had complained of backache and weakness in the left leg. In spite of her ability to walk from the car to the hospital, she was confident that she had poliomyelitis.

Neurologic examination revealed the cranial nerves to be normal. Motor status showed a questionable diffuse type of weakness in the left leg. The deep reflexes were equal and active. Superficial reflexes were present, without any abnormal forms. Sensory status was normal.

The patient, who was reassured that she did not have poliomyelitis, was obviously relieved emotionally and left the hospital secure and symptom free.

CASE 3 E B, a 23-year-old housewife, was seen at the hospital because of the loss of motor power in both legs, particularly the left.

Ten days prior to admission the patient had experienced an upper respiratory infection, from which she had appeared to recover. On the day before admission, she had gone to a celebration in a neighboring town and had returned that evening extremely tired. Shortly after going to bed, she became concerned because she was unable to move the left leg, and later noticed weakness in the right. The past history revealed that at the age of 12 she had had an episode of weakness in both legs, and during the course of her life there had been many manifestations of neurotic behavior.

On admission the temperature was 97.4°F. The patient did not seem to be under any particular tension and was quite composed. Neurologic examination showed the cranial nerves to be normal. Motor status revealed normal motor power in the upper extremities, but in both legs there was a weakness associated with increased muscle tone, more marked on the left side. There was limitation in movement, flexion and extension of the toes. The deep reflexes were bilaterally exaggerated. The superficial reflexes were normal in type, without pathologic manifestations. There was a bizarre type of sensory loss in the lower extremities that did not conform to any peripheral or segmental pattern.

The patient was assured that she did not have poliomyelitis, but when the nature of her illness was explained, she found the explanation impossible to accept on a functional basis. Behind the conversion features were personal and emotional problems of which this patient had little, if any, conscious appreciation. She was discharged on the day of admission.

CASE 4 R S, a 24-year-old carpenter, was admitted to the hospital because of headache, stiffness in the neck and backache.

This patient had been exposed to a sister-in-law who had developed poliomyelitis about 3 weeks previously, and he came to the hospital greatly disturbed, the complaints mentioned above having developed on the preceding day.

Physical examination revealed a temperature of 98.8°F. The patient and his wife were obviously panicky and quite sure that the patient had poliomyelitis. Neurologic examination was entirely negative, except for some questionable stiffness in the neck. A lumbar puncture showed a normal spinal-fluid pressure, with 1 cell per cubic millimeter.

The patient was reassured that he did not have poliomyelitis, and the nature of the illness was explained to him. He was discharged on the day following admission.

*Associate professor in neurology and psychiatry, University of Nebraska College of Medicine; attending psychiatrist, Lutheran Hospital.

CASE 5 C. C., a 30-year-old housewife, was seen at the Douglas County Hospital because of inability to move the arms or legs.

The history disclosed that for several days the patient had been constipated and that on the morning of admission, while straining at stool, she passed a considerable amount of blood, which she described as making her feel weak and frightened. She lay down and was discovered to be feverish, and shortly thereafter called on a physician at his office. Because of the fever and muscle weakness, she was advised to report to the isolation ward. The past history was of significance, in that the patient had always been nervous and had just returned from a 3 weeks' stay at a hospital, where she had been treated for "nerves."

Physical examination revealed a temperature of 103°F, with redness of the throat. The patient appeared tense and apprehensive, expressing the hope that her children would not contract her illness. Neurologic examination showed the cranial nerves to be normal. There was a diffuse type of weakness of all four extremities that was slightly more marked in degree peripherally. The muscle tone was slightly increased. The deep reflexes of the arm were present and equal. The knee jerks were questionably present, and the left ankle jerk could not be definitely obtained. There was a bizarre type of hypalgesia in all four extremities that failed to follow any peripheral or segmental distribution. The sensory loss was more marked on the right side than on the left. Lumbar puncture showed a normal spinal-fluid pressure and 6 cells per cubic millimeter, without elevation in the protein.

It was explained to the patient that she had an upper respiratory infection, but not poliomyelitis, and the nature of the muscle weakness was described. With encouragement, she rapidly regained motor power and was discharged from the hospital after the pharyngitis had subsided.

DISCUSSION

A review of these cases reveals certain interesting correlations. Three patients had relatives who had developed poliomyelitis, 2 in the recent epidemic. Four had an elevation of temperature on admission, and all complained of pain either in the back or in the neck. In the 4 patients who showed weakness of one or more extremities, the weakness was associated with an increase rather than a decrease of muscle tone and with intact or exaggerated reflexes in all but 1. In 3 cases there were subjective or objective paresthesias. The recovery of motor power in all 4 cases was prompt following reassurance and an explanation of the nature of the illness.

A composite picture of the reported cases might be reconstructed as follows: a social attitude of marked anxiety precipitated by the development of poliomyelitis in the community, a marked intensifi-

cation of anxiety by the appearance of poliomyelitis in the family group, the development of concern about exposure, subsequent development of an upper respiratory infection, with attendant symptoms, as well as the somatic expressions of anxiety in the form of neck stiffness, tightness in the throat, feelings of suffocation and weakness; and finally a localization of the weakness in one or more extremities as a conversion symptom, with a prompt return of function on reassurance and explanation.

In the treatment of this group of cases, certain preventive measures deserve consideration. First of all, a factual presentation of poliomyelitis by the press is indicated. If a daily report is to be made, it might best be presented in an accessible part of the paper other than the front page, unless some emergency exists. A special effort should be made to appease any unreasonable fears of members in a family in which a case of poliomyelitis has developed. When the syndrome described above develops with hysterical paralysis or other neurotic features simulating a poliomyelitis, reassurance effects a prompt symptomatic cure. The response to reassurance and explanation in the cases in which there was marked fear because of association or exposure to patients with the disease suggests that the motor loss had as its basis an overwhelming fear, which caused a dissociation in motor activity. It is as though the patient had become "paralyzed with fear." The more usual conversion mechanism found in hysterical paralyses seemed to be responsible in Case 3. The depth of psychotherapy needed depends on the dynamics of the individual case.

SUMMARY

Attention is called to the existing social attitudes toward poliomyelitis and to individual reactions to this anxiety-provoking situation.

Five cases of suspected poliomyelitis are reported that had many features in common, 4 patients presenting hysterical paralysis of one or more extremities. The course in these cases is described.

The patient was reassured that he did not have poliomyelitis, and the nature of the illness was explained to him. He was discharged on the day following admission.

*Associate professor in neurology and psychiatry, University of Nebraska College of Medicine; attending psychiatrist, Lutheran Hospital.

dermatitis following the injection of 100,000 units of penicillin, no tests were done. Strickland³⁰ observed a patient who developed during a second course of penicillin treatment an immediate severe generalized urticaria and angioneurotic edema. No skin tests were performed. Binkley¹³ reported a case of dermatitis of the face with a negative intradermal test. When this patient was injected with 60,000 units intramuscularly, a papular dermatitis of the face, hands and feet followed and persisted for seven days. Flinn²¹ described a patient who suffered a severe urticarial reaction from injections of one brand of penicillin, although clinically and by skin tests he was not allergic to one of the other brands. One of Goldman's²⁷ cases developed vesicular dermatitis from parenteral penicillin and exhibited an urticarial skin test reaction, a tuberculin type of reaction and a positive patch test. A case of clinical contact dermatitis observed by Truitt²² demonstrated positive intradermal and patch tests followed in nine months by a tuberculin type of reaction. Graves²³ reported an acute vesicular reaction that began after the first injection of penicillin for a low-grade prostatitis and was followed by a superficial form of desquamation. This patient gave a positive intradermal test to 500 units of penicillin and to a 1:100 dilution of trichophyton. In a similar case the patient gave a negative intradermal reaction to penicillin and a positive reaction to the trichophyton extract. It was not decided whether the lesions were a manifestation of sensitivity to penicillin or some impurity in the penicillin solution used or were due to the too rapid liberation of toxic products from some unsuspected fungous or bacterial focus or to an alteration of local immunity that allowed dormant fungous spores to become active. In 3 of Goldman's²⁷ cases, with histories of recurrent mycotic dermatitis of the hands or feet, penicillin provoked a pompholyx-like dermatitis. It is interesting that of 17 patients with previous fungous disease observed by Cormia³ 88 per cent showed an immediate reaction to intradermal tests with penicillin, although none had been treated previously with penicillin. Lamb³⁴ reported a case of syphilis under treatment with penicillin in which the patient developed a vesicular eruption of the fingers, penis and crural areas and gave a positive wheal-reaction intradermal test to penicillin. Another patient who during the course of penicillin injections for actinomycosis developed a vesicular eruption of the crural region, scrotum and webs of the fingers presented a negative intradermal test to penicillin and trichophyton but a positive intradermal test to oidiomycin. In 10 cases of skin eruptions treated by penicillin, Heinlein³⁵ found that the drug caused a marked aggravation of the existing skin eruptions, frequently associated with the appearance at other sites of new similar cutaneous manifestations accompanied by systemic reactions. This phenomenon was considered a manifestation of

an underlying bacterial allergy. Price³⁶ reported a case of reaction to penicillin consisting of purpuric eruptions with subsequent wheals and arthralgia in which the patient gave a positive reaction to intracutaneous injections of serum with penicillin. Scratch and patch tests with penicillin solution were negative. Sullens³⁷ presented a case exhibiting urticaria, arthralgia and generalized lymphadenopathy that began six days after a second course of penicillin had been instituted; this patient presented a negative skin test to the penicillin solution, but the skin testing caused the appearance of urticarial lesions of the upper arm above the area of the test. Binkley's¹³ case of dermatitis from penicillin presented no epidermal or intradermal sensitivity by cutaneous testing, but the patient had a papular edematous eruption of the hands and feet after a test intramuscular injection of penicillin.

Rostenberg^{38, 39} found that 5.5 per cent of 144 subjects gave a tuberculin type of sensitivity reaction to penicillin although they had had no previous contact with the drug. This spontaneous sensitivity seemed to have no eczematous or wheal component. He also reported that properly spaced intradermal injections of penicillin could cause a tuberculin type of sensitivity to develop, during sensitization such patients may develop urticarial reactions. It was not possible to demonstrate a passive transfer of the sensitivity exhibited by persons who showed a tuberculin type of reaction on first contact with penicillin. Epstein¹¹ reported a case of delayed tuberculin-type, infiltrated, itching reaction to both commercial and crystalline penicillin in a nurse who presented a clinical picture of contact sensitivity. All patch tests were negative except when the solution was applied to a site that had previously shown the eruption. Truitt²² observed a case of clinical contact dermatitis with at first a positive immediate intradermal test but nine months later a positive tuberculin type of reaction. Clayton⁴⁰ presented a series of cases of presumed penicillin urticaria in which he was unable to obtain any positive penicillin tests. Likewise, 4 of 56 patients receiving injections of penicillin who developed allergic reactions resembling serum sickness were reported by Haswell⁹ as giving negative patch, scratch and intradermal tests.

CASE REPORT

A 52-year-old man, who had been hospitalized for 20 years with the diagnosis of dementia praecox, was admitted to the infirmary because of a cough and a fever of a few hours' duration.

Previous to the acute onset of these symptoms he had been free of any complaints, working about the hospital grounds every day. The family and personal histories were negative for asthma, hay fever, hives, eczema, angioneurotic edema or other symptoms suggestive of allergy. The record revealed that a dental check had just been completed, with negative x-ray studies for apical abscess or other dental infection. The patient had not been away from the hospital for months, and there was no contagious disease among his known contacts. There was no history of previous administration of penicillin.

ALLERGIC REACTION TO PENICILLIN

Report of a Case

EUGENE M. HOLDEN, M.D.*

AMHERST, MASSACHUSETTS

EXTRACTS prepared from various species of the dermatophytes show potent antigenic properties. Jadassohn,¹ using the Schultz-Dale technic, proved that pathogenic fungi contained not only species-specific antigens but also an antigenic fraction common to all species. Clinically, dermatologists have long been cognizant of explosive reactions from fungus toxins, manifested by generalized "ids" and by bullous eruptions. Therefore, it seemed probable that patients being treated with penicillin would exhibit allergic reactions, either to a common hyphomycetic allergin or to a specific penicillin allergin.

Reactions to penicillin are clinically infrequent, but do occur. A recent case focused attention on this subject and prompted a brief survey of the literature. Florey and Florey² encountered no reactions in 187 patients. In the 500 cases reported by the National Research Council,³ urticaria was observed in 28 per cent, whereas in 209 cases reported by Lyons⁴ the incidence was 57 per cent. Tests by Lyons for cutaneous and ophthalmic sensitivity during and after the reactive phase were negative, and precipitins were absent. Among the 182 patients of Stokes,⁵ skin eruptions appeared in 0.8 per cent. Fifty-nine per cent of the 1418 syphilitic patients treated by Moore⁶ exhibited Herxheimer reactions with fever and usually exacerbation of secondary skin lesions, and allergic eruptions appeared in 1 per cent. Dawson and Hobby⁷ found skin reactions in 3 of 100 cases. Cormia⁸ reported that of 2000 soldiers receiving prolonged penicillin treatment, 6 developed urticaria, 3 a serum-sickness syndrome, 2 erythematovesicular eruptions, 1 erythema nodosum, and 5 transient miliaria; skin tests were positive in 57 per cent of 116 persons tested. The development of symptoms of a low-grade fever, malaise, urticaria and transient edemas was noted by Haswell⁹ in 4 of 56 patients receiving parenteral penicillin. Herrell¹⁰ observed cutaneous sensitivity to skin tests in only 2 of 150 cases of clinical penicillin reactions.

The skin of many persons is known to be sensitive to various molds and mold products. Many cases of clinical contact dermatitis have been reported in the literature. Some of these may have been due to an underlying generalized, tuberculin type of sensitivity, such as that seen in the vesicular dermatophytids of the hands in patients with dermatophy-

tosis of the feet. According to Epstein,¹¹ involvement of the epithelium does not necessarily make an eruption a true eczematous contact dermatitis, and not all dermatitis that is brought about by external contact is immunologically of the contact type. Pyle and Rattner¹² reported a case of dermatitis venenata of the face and genitalia in a pharmacy officer who reacted strongly with a patch test of crystalline penicillin. A similar case was presented by Binkley,¹³ with a positive intradermal and patch test to the penicillin used. Satulsky,¹⁴ Markson¹⁵ and Bedford¹⁶ reported cases of dermatitis of the eyelids with positive patch tests. Silvers¹⁷ performed patch tests on a chemist with penicillin dermatitis of the eyelids and penis and found the test with commercial sodium penicillin positive, and that with crystalline sodium penicillin negative. Benkwith¹⁸ and Schultz¹⁹ observed allergic dermatitis of the eyelids from penicillin instillations, with positive intradermal and patch tests. Barker²⁰ reported the case of a medical officer who developed an acute dermatitis of the face while handling penicillin in laboratory and who exhibited a positive patch test to the penicillin solution but not after the solution had been autoclaved. Michie²¹ described an eczematous reaction to penicillin involving not only the ear being treated but also an almost healed leg wound to which penicillin powder had been applied. This patient exhibited a positive patch test. Vickers²² demonstrated by a case report that penicillin powder can cause a dermatitis when sprinkled on local abrasions; his patient also had a positive patch test. Kleinfeld,²³ Phillips²⁴ and Kern²⁵ reported allergic involvement of the palate and the pharynx in cases in which penicillin was administered orally; no patch tests were reported. Selinger²⁶ observed a dermatitis of the eyelids from penicillin eye drops, but the patch test was negative. Thirteen of 350 cases of various types of cutaneous lesions treated by Goldman²⁷ with penicillin ointment developed clinical contact dermatitis, 11 presenting positive patch tests.

In 1944 Crippe²⁸ reported a case of massive urticaria after the injection of 200,000 units of penicillin in a patient who exhibited a positive intradermal test to the penicillin but a negative intradermal test to the spores. Barker²⁰ presented another case of massive urticarial reaction after the injection of penicillin, with a positive intradermal test to the penicillin solution. Tests with autoclaved solutions were negative. Morris²⁹ reported a case of bullous

MEDICAL PROGRESS

PHYSICAL MEDICINE

ARTHUR L. WATKINS, M.D.*

BOSTON

DURING the war rapid developments occurred in the field of physical medicine. Activities included in this specialty have expanded to comprise more active and diversified treatment during convalescent stages of disease to ensure a speedy return of injured soldiers to combat or workmen to industry. In addition to widening, the field is also reaching greater depths through the establishment of research programs to investigate some of the fundamental problems of the effects of physical agents. Along with these advances it has become apparent that it is necessary for men to receive special training in physical medicine to understand properly the many different types of treatment to be prescribed and to direct adequately technicians, such as physical and occupational therapists and others working in rehabilitation. Special training is also necessary to aid in the proper integration of fundamental and clinical research in this field. Physical medicine can accordingly be said to have emerged as a distinct specialty, although the exact boundaries are still somewhat undefined. The need for specialists has far exceeded the supply. Only a few years ago less than fifty physicians in the country considered themselves as specialists, whereas at present approximately one hundred and fifty men are needed in the Veterans Administration and Army alone.

There has been considerable confusion in the use of terms designating workers in this field. At the time of World War I physiotherapy was the most familiar word, the technicians being known as physiotherapists. Later, the term physical therapy was more generally used, the doctor being designated as a physical-therapy physician, as distinguished from the physical-therapy technician. As the field broadened to include other types of treatment, such as occupational therapy and physical reconditioning, the technicians became known as physical therapists and occupational therapists, and the physician had no single term to indicate his specialty. The American Congress of Physical Medicine, the Society of Physical Medicine and the Council on Physical Medicine of the American Medical Association gave considerable thought to the coming of a suitable term to describe the specialist in physical medicine. The result of this is the word "physiatrist," which has now been quite generally accepted by those in the field of physical medicine but is still unfamiliar to the majority of

physicians and laymen. This term is derived from the two Greek words "physis," meaning physical or natural, and "iatria," meaning treatment.¹

The need for a great many more physiatrists is easily understandable when one considers that they are responsible for the medical direction of rehabilitation programs in the Army, Navy and Veterans Administration, as well as of civilian hospitals, community rehabilitation centers and many industrial medical clinics. This development of industrial rehabilitation, which is one of the most important aspects of physical medicine, is discussed in greater detail below.

The need for fundamental and clinical research has been recognized by many physicians, and the present status has been summarized in a previous paper of this series.² The report of the Baruch Committee on Physical Medicine emphasized the necessity of encouraging such research, and funds have been made available to aid scientists in this field. The work in the various centers devoted to research in physical medicine is still in its infancy but a few preliminary studies reported at the American Congress of Physical Medicine in September, 1946, are of interest.

There have been relatively few new developments in therapeutic technics in the past few years. Because of the interest in physical fitness in wartime, exercise therapy has received the attention of physiologists, psychiatrists and physical educationists, as well as that of the physiatrists. The results of some of their studies are reported below in the final section of this paper.

MILITARY REHABILITATION

Because of the acute manpower shortage occasioned by the war, the problem of returning injured workmen and service men to their former activities was attacked earlier in England than in this country. Since methods now being employed in this country are to a large extent adapted from those in use in England, it may be well to review briefly a recent paper by O'Malley³ describing rehabilitation in the Royal Air Force. There is considerable misunderstanding about the meaning of rehabilitation, but this author states "It denotes the restoration of the injured man to perform his duties — mentally, physically, socially, and technically — as efficiently as he did before he was injured. If we fail to make him equivalent, then he has to be resettled in another trade."

*Associate in Medicine, Harvard Medical School; chief of physical medicine, Massachusetts General Hospital.

Physical examination revealed a well developed man who was only moderately ill. The conjunctivas were slightly injected, the scleras were clear, and the pupils were round and regular and reacted to light and to distance. The ears were free of drainage, and the drums normal. The nasal passages were free of discharge, and the oropharynx showed no evidence of infection. There was no cervical adenopathy. Both lungs were resonant, there were a few rales, with an increase in bronchial quality to the breath sounds in the right axillary region. There was no demonstrable enlargement of the heart, the cardiac rhythm was regular, and there were no murmurs. Examination of the abdomen, skin and neuromuscular system was negative. The temperature was 104°F, and the respirations 24.

Examination of the chest showed a pneumonic lesion of homogenous density in the region of the right middle lobe that was diagnosed as lobar pneumonia. The remainder of the lung field was clear. Repeated throat smears and cultures revealed no pathologic organisms.

Examination of the blood disclosed a red-cell count of 3,830,000, with a hemoglobin of 85 per cent, and a white-cell count of 24,300, with 87 per cent neutrophils, 12 per cent lymphocytes and 1 per cent basophils. Repeated urinalyses were negative except for a rare pus cell. A serologic test for syphilis, repeated 3 weeks later, was negative.

The patient was placed on 30,000 units of penicillin every 3 hours. No other medicine was given. In 96 hours the temperature had descended to a normal level, and the chest was clearing clinically and on x-ray examination. On the 3rd day, a nonitching rash appeared, consisting of minute, closely packed red points, nonpapular in character, involving all portions of the body more or less simultaneously. The oropharynx and tongue exhibited no lesions. No adenopathy or vomiting was present. Rumpel-Leede's sign could not be elicited. After 24 hours the penicillin was discontinued, and the rash began to fade. Within 3 days, all erythema had disappeared, and extensive desquamation occurred, persisting for 5 days.

Contact patch tests with soap and with rubbing alcohol were negative. Passive transfer tests with commercial penicillin and crystalline penicillin produced, on the test subject, wheals with pseudopods that reached diameters of 2.5 cm in 20 minutes and persisted for about 1 hour; serum and penicillin controls gave only areas of erythema about 0.6 cm in diameter. It was not practical to do intradermal skin tests on the patient.

Pyle⁴¹ has stated that in 4000 cases treated with penicillin he saw no rash similar to that observed in the case presented above. Goldman⁴² noted a similar reaction in a physician. Moore⁴³ stated that among 25,000 patients in the nation-wide syphilis study there were perhaps 4 such cases.

A review of the literature suggests that penicillin should not be used for minor ailments. Patients who have previously been treated with penicillin and those who have had previous fungous infections should be closely watched. Skin testing should help to warn the physician of a potential allergic reaction, although not all physicians would agree with Cormia⁸ that an immediate reaction 10 cm in diameter contraindicates penicillin therapy. In general it is a wise policy to begin a course of penicillin injections with small dosages, to prevent possible aggravation of foci of infection. If the patient has areas of fungous infection, they should be treated locally at the same time as the penicillin is administered intramuscularly. When penicillin is used topically or administered orally the possibility of a contact type of sensitivity should always be kept in mind.

SUMMARY

A review of the literature on allergic reactions to penicillin is presented, and a case of an apparent reaction is described. Caution in the administration of the drug for minor ailments is stressed, and the value of skin tests for sensitivity is discussed.

each with its own branch office and full-time physician in charge of physical medicine and medical rehabilitation. The branch areas similar to the central office have consultants, if possible, for physical medicine and rehabilitation in each area. Further subdivision is on the level of the hospitals, in which a chief of physical medicine is responsible for rehabilitation. Under him is an executive officer ordinarily with experience in rehabilitation in the Army or Navy. Technical services are divided into various categories, such as physical therapy, occupational therapy, physical reconditioning, educational retraining and shop retraining. The chief of physical medicine is responsible for prescribing treatment for patients in one or all of these sections, depending on individual physical and mental needs. Only physical and occupational therapists who are properly qualified may receive professional ratings and are given new appointments. Members of the technical staff in physical reconditioning, shop retraining and educational retraining are also required to have special qualifications by education and previous experience in these fields.

It is apparent that a more varied and graded treatment is available for convalescent patients in the Veterans Administration than in any civilian hospitals, with the possible exception of the better mental institutions. The success of this program can be achieved only when the entire medical staff is aware of its existence and cognizant of the proper selection of patients for referral. Plans have therefore been made to establish regular rehabilitation conferences of representatives of the various units mentioned above, together with social-service workers, psychiatrists, psychometrists and the ward officers, so that a total plan of rehabilitation can be mapped out for the patients. Further education of the general-hospital staff is provided by staff conferences and bulletins. Because the value of this rather elaborate and expensive setup for rehabilitation can be measured only by results, all the chiefs of physical medicine have been asked to devise new forms for recording progress and results. By this means new records now being distributed may, if properly utilized, help to evaluate the success of this important work.

The most rapid progress has been made in the mental institutions where the members of the staff are already familiar with many of the procedures of rehabilitation, such as shop work. The difference in the present goal, however, is that this type of therapy is aimed at directing the patient toward economic independence and complete social as well as physiologic recovery. Contacts with industry are therefore made, and already an appreciable number of patients have successfully taken their place in industry from mental hospitals as a direct result of this rehabilitation program.

At present, the plan of organization calls for physical and occupational therapy, physical reconditioning,

shop retraining and educational retraining in the various types of hospitals, such as general medical and surgical, tuberculosis and neuropsychiatric. It is too early to determine exactly the significance of the treatment, but the psychiatrists are doing clinical research to evaluate the results in the different types of hospital.

It is also the plan of the Veterans Administration to affiliate the hospitals whenever possible as teaching units of adjacent medical schools. This should be of benefit for the medical schools as well as for the Veterans hospitals, particularly in physical medicine, since the students will be able to see rehabilitation in action.

CIVILIAN REHABILITATION

There is considerable statistical evidence that rehabilitation of industrial casualties and other civilians with physical handicaps is financially sound. In the relatively few cities in the United States where community rehabilitation centers are already established, much is being achieved by treatment of the injured patient during convalescence after the acute surgical stage, bringing him on to the point of re-employment. An apparent growth of social responsibility for the disabled is manifested by the Vocational Rehabilitation Act, which provides for the purchase of medical and surgical services for physical restoration of patients who may become employable by such treatment and are in financial need. There are, however, insufficient facilities at present to provide these services, since the average civilian hospital is not equipped to render treatment during the entire convalescent period because of lack of physical facilities and trained personnel. Physicians in general are little acquainted with the possibilities of such treatment and still refer patients to such facilities, even when available, only after months of ineffectual treatment. The medical schools, in general, are also doing nothing to train future physicians in this type of service.

Experience obtained from centers established in England and in the armed forces in the United States has made it possible to outline functional physical medicine and medical rehabilitation adaptable to civilian practice¹⁴⁻¹⁶. The first point is the introduction of physical reconditioning into every ward from the first stage of recovery from disease or injury, without allowing the patient the mental and physical deterioration from excessive inactivity. The second point is establishment of a plan of convalescence to speed recovery of physical and psychologic function. Thirdly, the form of treatment for rehabilitation must be adapted individually for the patient's disability as measured by careful functional tests. Another important point in the success of treatment is personal supervision by a properly trained physician through the entire program, that is, until the patient is placed in society and industry, when possible.

The basic principles on which this plan of rehabilitation is organized are those of a system of restoration of mental and physical functions by physical and mental activity. It has been stressed that the art of rehabilitation is making the patient do his exercises regularly, efficiently and, above all, willingly, since there is no greater fatigue than that of boredom. The mental problem in rehabilitation is repeatedly emphasized. For this reason, it has been advocated that the center be functionally allied to hospitals, although geographically separate, so that the patient may be stimulated to self-endeavor in an atmosphere of enthusiasm coupled with a feeling of well-being, rather than the atmosphere of a hospital. It is taken for granted that there is continual progress and enthusiasm in such centers. O'Malley advocates a residential center accommodating 200 to 250 patients. Of the accommodations necessary beyond that of domestic facilities, first and foremost is a large gymnasium. In connection with this are the doctors' consulting rooms, secretaries' offices, cafeteria, physical-therapy rooms, swimming pool, rest rooms and sun terraces. Smaller gymnasiums are also advised for more individual treatment of patients with acute injuries. Outside the gymnasium there should be playing fields and also a library and other recreational facilities, such as a hall for dances, motion pictures, lectures, concerts and theatricals. Because the success of the work depends so much on the morale of both the staff and the patients, the right type of leadership and personality in the staff is stressed. Proper reception of the patients is thought to be of considerable importance on the principle "that if you want to keep a cat in the house you must butter its feet." Attempts at establishing a proper *esprit de corps* are begun at once.

The organization of the staff in this center consists of a commanding officer, or director, and three medical officers for each 250 patients. Under them are the physical-fitness officer and physical-training instructors, who are responsible for the exercise classes. The patients are classified according to injury groups, of which there are four main divisions — two in which the lower limbs are involved, and one each for injuries of the arms and spine — that, in turn, are graded according to degree of convalescence and ability to perform exercises. Physical therapists are used, but the emphasis is on exercise rather than on passive procedures, the early groups exercising first on the anatomic and later on the functional approach and finally for maximum efficiency. In the occupational-therapy section the work is partly diversional and partly remedial, aiming toward vocational training.

Remedial exercises have been divided into a direct and an indirect approach, the former comprising the exercises and treatments in the physiotherapy room, with a maximum time limit of about thirty minutes for this type of treatment, and the latter

including swimming, cycling, clay-pigeon shooting, archery, roller skating, and games such as badminton and volley ball. The responsibility of grading, which is an important function, is left to the medical officer, since it has been found that premature removal of a patient into more advanced groups is as harmful as too prolonged periods in low groups.

The mental and social aspects are thought to comprise nearly 75 per cent of the problem, and the solution is afforded by the environment of the center and the personalities of the staff, as well as by a proper design for living — that is, a balanced program including light recreational activities together with more serious educational and vocational guidance.

The results of this program are of interest. In the unit reported by O'Malley approximately 10,000 injured persons were seen in a three-year period, 92 per cent of the injured air crews returned to duty, 64 per cent to the actual operation of flying, and 84 per cent of the technicians returned to their trade. In view of these results similar ventures are advocated for civilian life, and many of these are in actual operation.

Programs for convalescent care and rehabilitation in the Army Air Forces, Army and Navy have received considerable publicity in the medical and lay press.⁴⁻¹¹ The treatment for the convalescent patient starts while he is still in bed with physical reconditioning composed of short daily periods of light bed exercise designed to allay muscle atrophy in parts of the body not diseased or injured. At the same time educational reconditioning is begun, including organized lectures and group discussions. Thirdly, occupational therapy, consisting of light purposeful tasks, creative art or handicraft, such as leather working and wood carving, has been found of assistance in restoring function and is of benefit for morale. For ambulatory patients physical reconditioning is more strenuous, including calisthenics, gymnastics and athletic sports. At the same time the occupational therapy is graded for heavier work. Finally, physical training leads to conditioning for extreme physical exertion, and the educational retraining directs the patient by refresher courses in military training, including map reading, scouting, use of weapons and so forth. This educational retraining is adapted to the special needs of the patient.

REHABILITATION OF VETERANS

The rehabilitation of veterans is a problem of general interest, and the plans now in operation are worthy of more detailed consideration.^{12, 13} The organization includes a central office in Washington in charge of physical medicine and medical rehabilitation that receives the advice of a national consultant. The country is then divided into branches roughly corresponding to the Army areas,

et al²⁵ from tests on normal control subjects. The conclusions, in part, were as follows:

The most important single element in the intensification of the daily volitional work output is the will to perform with physiologically maximum effort. Augmentation in strength through daily exercise is associated with significant increase in the work done on the limit day. The rate of improvement in work capacity is rapid under a program of heavy resistance exercise. Strength may more than double in four weeks with systematic training. There is no evidence of significant loss in the kind of increase in work capacity which is acquired by heavy resistance exercise during the post-exercise period which exceeds in duration the initial period of training. The ability to perform work may continue to improve after the cessation of systematic training. This phenomenon suggests changes of an unexplained kind associated with motor learning among which must be included significant extension of the psychological end point of fatigue.

In view of these early reports of success in this method of exercise therapy, a study of its use in various pathologic conditions is warranted. Its possible value in the treatment of poliomyelitis is at present being studied.

Other specialized exercise technics have been developed in the therapy of diseases of special parts of the body. For example, systematic preoperative and postoperative exercises have been found to be of value for patients subjected to chest surgery, particularly thoracoplasty. The greatest success is obtained when exercises are started preoperatively with explanations to the patient of what his postoperative problems will be. These include the mobility of the shoulder and scapula and the function of the supporting musculature of these parts, proper breathing and posture. Actual details of procedures to be used have been reported by several authors.²⁶⁻²⁸

Correct posture and body mechanics has continued to receive the interest of orthopedists and physical therapists, particularly because of its preventive implications.²⁷ Quantitative methods of evaluation have been described.²⁸ The dynamics of posture have been emphasized by Howarth.²⁹ He pointed out the changes during infancy, childhood and adult life and the variations in sitting, standing and lying positions that are generally encountered. The advantage of good basic dynamic position is stressed in athletics as well as in everyday life, and the acquisition of such control is thought to be rewarding in the reduction of fatigue, avoidance of accidents and even as an "approach to life."

One aspect of therapeutic exercise is instruction of patients in the use of crutches. Although the usefulness of these aids to ambulation is generally accepted, little information is readily available in the literature for instruction of students, physical therapists, patients or physicians. Deaver and his associates³⁰⁻³² have recently published detailed articles with illustrations showing the proper use of crutches for various conditions. These papers have also been reprinted in a monograph that is a

definite contribution to the literature of physical medicine.

COMBINED DRUG AND PHYSICAL THERAPY

Other procedures in physical medicine that have received considerable attention include the combined use of certain drugs that have an effect on neuromuscular function and exercise therapy. Curare which is known to have an inhibitory effect on neuromuscular transmission, has been used to reduce spasticity in central-nervous-system diseases, such as hemiplegia and infantile cerebral palsy. To provide for prolonged effect a suspension of curare in a mixture of peanut oil and wax has been said to provide relaxation of muscle spasm up to three days' duration.³³⁻³⁵ With such a method of administration the unpleasant side effects were absent. Maximum benefit from the drug was obtained when physical therapy was also administered to increase function when spasticity was reduced. This combination of curare and therapeutic exercise, according to Schlesinger,³²⁻³⁵ is most effective in cases in which some voluntary function is present, rather than in paraplegic patients with spasticity and no active motion.

Schlesinger and Ragan³⁴ have also reported beneficial effects from curare in the treatment of muscle spasm of other origin, particularly that associated with acute low-back pain. Jones³⁵ states that curare may be used to help in the differential diagnosis of muscle spasm of reflex origin from that due to organic changes in limitation of passive motion or in the joints. It has also been suggested that curare is of value in the differentiation of pain due to nerve-root irritation and that secondary to inflammation of joints and surrounding tissue; the former is not affected by curare, and the latter is relieved. Although considerable lax excitement has been instigated by reports of remarkable success from this combination of curare and physical therapy in the treatment of spastic conditions, in my opinion its true worth will be known only after careful clinical analysis. Almost all patients who have previously had little or no treatment are benefited when given systematic physical therapy, particularly when their hopes are keyed up so that co-operation in the program is good. Just how much of the success of treatment is dependent on curare and how much on the physical therapy and how much is due to the combination will be known when more complete reports are published.

Curare has also been used in the treatment of infantile paralysis in a few clinics, with conflicting reports.³⁶⁻³⁷ The rationale of using a drug that is known to cause loss of voluntary muscle control in a disease that causes flaccid paralysis of muscles is not apparent to most physicians. Although it may be possible to relieve meningismus and other types of muscle hyperirritability present in the acute stage,

One of the simplest and most obvious means of combating disuse atrophy from bed rest has been the adoption of early rising following surgical procedures and in the puerperium. A number of reports on this subject have appeared in the literature, the consensus being that early rising is not dangerous but, in fact, reduces the incidence of complications, particularly those of thrombophlebitis and phlebothrombosis with pulmonary emboli. Convalescence is markedly speeded by this practice, which is of special value in these times of shortage of hospital beds.¹⁷⁻²² In addition to early rising, leg exercises with special mechanical apparatus have been devised, particularly to reduce the incidence of pulmonary embolism secondary to venous thrombosis.²³ It has also been pointed out that simply getting the patient out of bed is not sufficient to protect against venous clotting, for to allow a patient to sit in a chair with the legs dependent causes greater circulatory stasis in the veins of the lower extremity than that produced if he contracts his musculature actively against resistance lying in the horizontal position. Early rising and ambulation, to be effective, require that the patient walk.²⁴

The principle of separation of the rehabilitation from the hospital has been stressed in the armed forces for reasons of morale. As Hellebrandt²⁵ has pointed out, this separation is less urgent in civilian practice, where much may be gained by the close supervision of a resident medical staff if the rehabilitation section is connected with the hospital. A physical-medicine specialist in constant attendance is desirable for proper supervision of the treatment. Because of the tradition of not allowing patients to do things for themselves in general hospitals, some changes may be necessary in rehabilitation wards, as pointed out by Deaver.¹⁷ He has emphasized the importance of functional education to teach fundamental activities and skills beginning with the most commonplace and humble acts. Patients such as paraplegics and hemiplegics may be graded according to their ability to perform the everyday activities of life, and simply by the act of grading performances their competitive spirit may be aroused, with the result that they are stimulated to more rapid recovery.

One of the most striking advances in rehabilitation concerns the treatment of patients paralyzed by injuries of the spine—that is, the paraplegic patients.²⁶⁻²⁹ Special services to take care of these patients were developed in the armed forces, where the importance of teamwork was emphasized. The surgical care was handled by the neurosurgeon, orthopedic surgeon and urologic specialist. The patient must also be watched carefully for general nutrition by the medical specialist, and his skin taken care of by the nursing staff. With proper treatment it has been found possible to save the lives of paraplegic patients and, with the help of the medical-rehabilitation department, to teach the ma-

jority to be self-sufficient to a remarkable degree. Most of them can be taught to walk with crutches, even those with severe flexor spasms being relieved by anterior rhizotomy.³⁰ Compensatory development of the upper extremities, under the supervision of physical rehabilitationists, aids the patient in learning to walk under the direction of a physical therapist. Skills are developed first by the occupational therapist, and later in the shop retraining department, so that actual vocational training is achieved. Contacts with industry have been made in many of the hospitals so that patients may be gainfully employed while still in the hospital and on discharge. Morale has been fortified by grouping patients with similar injuries in centers where improvement is placed on a competitive basis, including individual scoring systems.

Centers have also been admirably developed for the care of amputees. Again, general physical development is stressed, and proper use of prostheses taught, including ambulation and vocational training.³¹ There are, however, many more amputees in civilian practice than resulted from war injuries, and the fine results achieved in service hospitals remain as a challenge for better treatment in civilian practice.

NEW TECHNIQUES

In view of the considerable emphasis on rehabilitation, particularly early return of function in diseased and injured extremities, it is understandable that the greatest interest in physical-therapy techniques has recently concerned exercise therapy. The method that has perhaps attracted the most attention is that of systematized weight lifting adapted to therapeutic exercise. DeLorme³² developed in the Army a program of heavy-resistance, low-repetition exercise based on the technic of weight lifters. This was found to be extremely effective in developing muscle strength following traumatic lesions of the bones, joints and surrounding tissues. This system of training can be briefly summarized as follows: individual exercises with a load heavy enough to preclude more than ten to fifteen successive contractions, an increase in resistance as soon as the load can be lifted ten consecutive times with ease, periodic attempts to surpass and improve the maximum performance, and rest periods in relation to the day of maximum performance for testing.

Applying these principles of weight lifting, DeLorme devised an apparatus that was mechanically suitable for exercising all the major muscle groups of the trunk and extremities. He reported signal success in increasing strength of the muscle groups so exercised, together with actual hypertrophy as judged by circumferential measurements.

It is well known that such methods, although empiric in origin, are successful in developing the strength of normal persons. Some investigations to explain these results have been made by Houtz

physical fitness, and there was similarly a higher increase in lactate following a grip test, with an output of more electric discharges from the muscles when measured electromyographically.

The search for improvements in measurements of fitness still continues, one of the most recent being based on the change in the reduction time of blood after breath holding.⁶⁰ Others have emphasized the value of skill and the psychologic factors in evaluating working capacity, particularly of the physically impaired. Such measurements are essential to the successful working of rehabilitation programs resulting in correct placement in industry.⁶¹⁻⁶³

Electrophysiology

Studies are still reported on technics of electric stimulation and the effects of such stimulation on atrophy of denervation and disuse. Many different wave forms have been used for stimulating nerve and muscle, such as the sine wave, exponentially following currents, inductive impulses and square waves. Offner⁶⁴ calculated on the basis of heat production that that wave form causing excitation with minimum injury was an exponentially rising current. Because such a current is not readily produced by simple electronic circuits, the next best wave form for clinical use is the square wave, sine waves being the least efficient, requiring 85 per cent more power than the most efficient type.

Fischer and Ramsey⁶⁵ found that daily electric stimulation of denervated rabbit muscle was effective in retarding weight loss and deterioration of muscle protein. Treatment applied against high resistance was more effective than when the muscle contracted freely or against little resistance. A study of protein concentration and atrophy due to tenotomy disclosed that the changes were practically the same as those following denervation.⁶⁶ The atrophy of demobilization alone was nearly as great as that from the other two conditions, but the total protein concentration loss was only about a third. Ko man, Osborne and Ivy⁶⁷ also found that appropriate electric stimulation favorably altered the course of degeneration after crushing of the sciatic nerve in rats. Young⁶⁸ reported that muscle atrophy developed in the absence of either stimulation from above or resistance from below, both factors being essential for hypertrophy. Massage of denervated muscle, according to Sushind et al.,⁶⁹ caused only slight retardation of weight loss but was effective in maintaining the strength. Electric stimulation retarded weight loss but exerted no effect on the contractile strength per unit mass of muscle. It was concluded that effective therapy for treatment of paralyzed muscles is a combination of electric stimulation and massage.

its value in reducing residual paralysis can be determined only by further study

Neostigmine (prostigmine) is another drug that has recently received a great deal of publicity because of reported benefits in relieving muscle spasm, particularly when combined with the usual types of physical therapy. There can be no doubt that this drug acts to stimulate the intestinal tract and has striking clinical beneficial effects in relief of the symptoms of myasthenia gravis. The increase of muscle strength, which is striking in these patients, is thought to be due to the inhibition of cholinesterase, which is the agent destroying acetylcholine, an important factor in neuromuscular transmission. The action is primarily at the myoneural junction, but there is some evidence of effects in spinal centers, particularly relief of spasticity in patients with spinal-cord disease or hemiplegia. This drug has accordingly been tried in a wide variety of diseases in which there is evidence of muscular spasm, spasticity, cramps or pain. One group has reported beneficial results in poliomyelitis, rheumatoid arthritis, cerebral palsy, hemiplegia, facial paralysis, subacromial bursitis and similar conditions as judged by clinical response, together with the use of physical therapy.^{48, 49} Clinical appraisal of beneficial results seems to be lacking in the early reports, and, as is often true, later studies are beginning to show negative results—for example, in the treatment of rheumatoid arthritis.⁵⁰

RESEARCH

Fitness Tests

Although research in physical medicine has recently been reviewed, the increasing emphasis on exercise therapy justifies a summary of some of the latest studies on testing physical fitness. Physical-training programs were developed to a remarkable degree during the war with the hope of increasing capacity for physical exertion and also efficiency in activities not requiring much physical exertion, such as piloting aircraft. To assess the value of these programs it is necessary to develop methods of measuring physical fitness. This subject has been reviewed by Johnson,⁵¹ of the Harvard Fatigue Laboratory. He has pointed out that if unquestionably fit and unfit men of similar stature are compared while performing the same work, which they are able to sustain in a steady state, the fit men show a greater oxygen consumption, a slower pulse rate, a lower systolic blood pressure, a larger stroke volume and a lower blood lactate during work and a faster return of the blood pressure and pulse rate to resting value after work. If the work is too much to be maintained steadily, the fit man shows a longer duration of effort before exhaustion, a higher oxygen consumption, a somewhat slower maximal pulse rate, a larger stroke volume, a higher blood lactate and a faster return of the blood pressure to normal after work. In other words, the man who was said to

be fit carries on moderate work with less disturbance of physiologic equilibrium. When forced, he can displace this equilibrium farther and for a longer time, and his recuperative powers are such that after exhausting exercise he returns to normal more quickly.

The physical-fitness tests most widely used tax the cardiovascular system by exercises involving large muscle groups without demanding unusual types of skill, as in the step test, treadmill and bicycle ergometer.^{52, 53} The most frequent measurements are oxygen consumption, pulse rate, blood pressure and blood lactate. An important difficulty in all such measurements is that the patient must have motivation to do well. The ideal test would therefore eliminate the psychologic factor. These tests have been used fairly successfully in the measurement of physical conditions before and after periods of training. The conclusions from these studies are that it is impossible at present to predict by a single examination how much a given subject is capable of improving with training and that men in reasonably good condition at the start of the program require more vigorous training to improve significantly than men in poor condition.⁵⁴

Significant clinical applications of these physical fitness tests have been made in progress of rehabilitation and convalescence. Landis⁵⁵ has pointed out the value of adjustment to the peripheral circulation encountered during convalescence. His physiologic analysis gives weight to the importance of early supervised exercises performed by patients while still in bed, followed by more active physical reconditioning during convalescence. Karpovich, Starr and Weiss⁵⁶ reported speeded convalescence by physical-training programs during which the degree of activity was determined by graded step tests. Physical-fitness tests have also been used in studies of neurocirculatory asthenia, effort syndrome and fatigue states. During exercise on the bicycle ergometer it has been found by some workers that there was a significantly poor exercise response in the psychoneurotic patients as compared with normal controls.⁵⁷ Oxygen uptake, lactate rise and pulse rate were determined, and oxygen consumption was considered the most satisfactory quantitation of exercise response. Cohen et al.⁵⁸ observed abnormally small displacement of homeostasis with maximal effort and abnormally large displacement with moderate work, indicating poor physical condition. They suggested that this intolerance to effort was due to constitutional inferiority. Both psychologic and physiologic studies in psychoneurotic patients complaining chiefly of fatigue were carried out by Watkins and his associates,⁵⁹ who noted that certain psychologic states seemed to precipitate or consistently preceded the onset of fatigue. In the same group of patients submaximal work on the bicycle ergometer was accompanied by abnormally high lactate values that may have indicated poor

physical fitness, and there was similarly a higher increase in lactate following a grip test, with an output of more electric discharges from the muscles when measured electromyographically.

The search for improvements in measurements of fitness still continues, one of the most recent being based on the change in the reduction time of blood after breath holding.⁶⁰ Others have emphasized the value of skill and the psychologic factors in evaluating working capacity, particularly of the physically impaired. Such measurements are essential to the successful working of rehabilitation programs resulting in correct placement in industry.⁶¹⁻⁶³

Electrophysiology

Studies are still reported on technics of electric stimulation and the effects of such stimulation on atrophy of denervation and disuse. Many different wave forms have been used for stimulating nerve and muscle, such as the sine wave, exponentially following currents, inductive impulses and square waves. Offner⁶⁴ calculated on the basis of heat production that that wave form causing excitation with minimum injury was an exponentially rising current. Because such a current is not readily produced by simple electronic circuits, the next best wave form for clinical use is the square wave, sine waves being the least efficient, requiring 85 per cent more power than the most efficient type.

Fischer and Ramsey⁶⁵ found that daily electric stimulation of denervated rabbit muscle was effective in retarding weight loss and deterioration of muscle protein. Treatment applied against high resistance was more effective than when the muscle contracted freely or against little resistance. A study of protein concentration and atrophy due to tenotomy disclosed that the changes were practically the same as those following denervation.⁶⁶ The atrophy of demobilization alone was nearly as great as that from the other two conditions, but the total protein concentration loss was only about a third. Bowman, Osborne and Ivy⁶⁷ also found that appropriate electric stimulation favorably altered the course of degeneration after crushing of the sciatic nerve in rats. Young⁶⁸ reported that muscle atrophy developed in the absence of either stimulation from above or resistance from below, both factors being essential for hypertrophy. Massage of denervated muscle, according to Suskind et al.,⁶⁹ caused only slight retardation of weight loss but was effective in maintaining the strength. Electric stimulation retarded weight loss but exerted no effect on the contractile strength per unit mass of muscle. It was concluded that effective therapy for treatment of paralyzed muscles is a combination of electric stimulation and massage.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C CABOT

TRACY B MALLORY, M.D., *Editor*

BENJAMIN CASTLEMAN, M.D., *Associate Editor*

EDITH E PARRIS, *Assistant Editor*

CASE 33211

PRESENTATION OF CASE

A forty-six-year-old restaurant manager entered the hospital because of dyspnea and swelling of the ankles.

The patient had been well until two and a half years before admission, when he suffered from the gradual onset of marked dyspnea, moderate ankle edema, easy fatigability, orthopnea and attacks of nocturnal dyspnea. After six months he consulted a physician, and under bed rest, digitalis and intravenous diuretics the symptoms subsided. Five weeks later he resumed work but continued to have moderate dyspnea without ankle swelling until four months before entry, when all the former symptoms gradually returned. He was, however, able to continue his job until a month before admission, when the symptoms became so severe as to force him to bed. Brief attacks of nocturnal breathlessness occurred almost every night. The edema failed to disappear on bed rest, but never extended above the ankles. The patient became extremely anorexic, was unable to sleep well and needed three or four pillows. Over a two-year period there had been occasional episodes of coughing productive of yellow mucus with moderate exacerbation in the last month. There

was no history suggesting rheumatic fever, syphilis or hypertension.

Physical examination disclosed a patient who was sitting in bed in slight respiratory distress and coughing frequently and forcefully. The lungs were resonant and clear. The cardiac border extended to the anterior axillary line in the seventh intercostal space. Thrills were palpable at the apex and in the third and fourth interspace to the left and right of the sternum. A high-pitched Grade IV systolic murmur, followed by a low, rumbling diastolic murmur, was audible at the apex. Along the left sternal border there was a harsh Grade IV systolic and loud, high-pitched diastolic murmur. The rhythm was regular, and the rate 75 per minute. The liver edge extended 3 cm below the right costal margin and was tender and firm. The spleen was not palpable. There was moderate edema over the lower portion of the back and marked edema of the legs. The feet were warm.

The temperature was 98°F, the pulse 76, and the respirations 16. The blood pressure was 106 systolic, 80 diastolic.

Examination of the blood revealed a red-cell count of 4,300,000, with a hemoglobin of 13.8 gm per 100 cc, and a white-cell count of 12,500, with 74 per cent neutrophils. The urine gave a ++ test for albumin, the sediment contained an occasional white cell only. The nonprotein nitrogen was 45 mg, the fasting blood sugar 95 mg and the total protein 5.4 gm per 100 cc.

Treatment consisted only of bed rest, mild sedation, ammonium chloride and continuance of digitalis. During the second night in the hospital the patient was unusually restless. The next morning he looked poorly, he was sweating profusely and felt weak. Physical examination revealed no change except that the pulse was totally irregular and the blood pressure was 112 systolic, 102 diastolic. Two or three minutes after being examined the patient

suddenly had a tonic convulsion and died. On application of a stethoscope to the chest within thirty seconds after the onset of the convulsion no heart sounds could be heard.

DIFFERENTIAL DIAGNOSIS

DR SYLVESTER MCGINN: It seems to me that the diagnosis in this case revolves around an interpretation of the thrills and the murmurs. As the heart sounds are recorded in this abstract considerable desirable information is lacking. For instance I should like to know about the pulmonic second sound and whether or not it was accentuated enough to suggest pulmonary regurgitation.

DR TRACY B. MALLORY: I carefully looked through the record for that information but could not find it.

DR MCGINN: I should like to know about the timing of the thrills.

DR MALLORY: Can you answer any of these questions, Dr. Bland?

DR EDWARD F. BLAND: No.

DR MCGINN: Cyanosis is not mentioned, I assume that it was not observed. A productive cough had been present for two years but there is no record of a sputum examination which I again assume was not done. The x-ray studies might be helpful, and the cardiologist finds some solace in electrocardiograms. I am sure that electrocardiograms were not taken since we are not given that information. I should like to know the albumin-globulin ratio. Occasionally, with edema of the lower legs, lipoid nephrosis is present. In this case the urine showed a ++ test for albumin, but I think that we have other information that will probably account for the diagnosis without the several things that I have made reference to. It is apparent that left and right ventricular failure was present, the cardiac asthma and nocturnal dyspnea being indicative of weakness of the left side of the heart and the engorged liver and the edema being indicative of right heart failure. Constrictive pericarditis could give the appearance of right ventricular failure, but in that condition the patient is usually not orthopneic, on that basis I believe that this diagnosis can be excluded.

Thrills may be due to valvular heart disease or congenital lesions and sometimes occur with acute dilatation of the heart. Acute dilatation can be due to acute rheumatic myocarditis or adhesive pericarditis or may represent the dilatation that is terminal in a large hypertrophied heart. It is difficult to believe that it was present in this case with a pulse rate of only 75. The temperature was normal. I think that there was something beyond acute dilatation to explain the thrills.

There are several kinds of systolic thrills, but when a thrill is maximal in the third or fourth interspaces, one thinks first of a congenital anomaly such as Roger's disease or an interventricular septal defect, in such cases, however, the heart is usually small.

The heart in this case was large. The location of the thrill could go with a pulmonary stenosis. In pulmonary stenosis the thrill is generally felt in the second left interspace and in most cases of pulmonary stenosis cyanosis is such a marked feature that it is included in the record of the examination. The thrill of aortic stenosis in the early stage is located in the second right interspace as a rule, but as cardiac hypertrophy progresses it is possible for the thrill and the murmur to be displaced downward even to the third and fourth interspaces. The thrills in this case were not timed but the most frequent apical thrill is the diastolic thrill of mitral stenosis. Occasionally diastolic thrills occur at the left sternal border, but if so they are due to rupture of the aortic-valve cusps, a rare condition. The description of the murmurs at the apex in this case report signifies mitral regurgitation and mitral stenosis and I think that they must be accepted as such. We must account for systolic and diastolic murmurs at the left sternal border which might have been due either to pulmonary stenosis with regurgitation or to aortic stenosis with regurgitation, probably the latter. There is no indication that the systolic murmur was transmitted to the neck. I think that that finding would tend to clinch this diagnosis. Left ventricular failure is evidenced by the history of cardiac asthma and right ventricular failure by liver enlargement. The statement that the cardiac border was in the seventh interspace at the anterior axillary line indicates an extremely large heart. Death was apparently primarily cardiac. I do not believe that it was embolic. The heart sounds were inaudible when the patient was examined within thirty seconds after death. The arrhythmia that preceded the exitus was probably due to coronary insufficiency and ventricular fibrillation. The possibility of a pulmonary embolus in congestive heart failure is great. It is my impression that the outstanding lesion in this case was aortic stenosis of high grade and with calcification of the valve. The location of the murmur and the thrill bears this out, as does the small pulse pressure, the low blood pressure and the regular rhythm. Patients with mitral stenosis in congestive failure are usually fibrillating unless some other lesion is predominating.

Finally we must consider the mode of death. Patients with aortic stenosis often die suddenly. I do not know whether or not there was interference with the coronary circulation.

CLINICAL DIAGNOSES

Rheumatic heart disease
Aortic stenosis and regurgitation
Mitral regurgitation and () stenosis
Congestive failure

DR MCGINN'S DIAGNOSES

Rheumatic heart disease
Aortic stenosis and regurgitation with calcification

Mitral stenosis and regurgitation
 Cardiac hypertrophy
 Congestive failure, left and right ventricles

ANATOMICAL DIAGNOSES

Calcareous aortic stenosis
Congenital bicuspid aortic valve
Hypertrophy of left ventricle, marked
Deviation of interventricular septum ? Bernheim syndrome
 Mural thrombi, left and right auricles
 Pulmonary embolus, small, left upper lobe
 Chronic passive congestion, lungs, liver and spleen
 Pancreatitis, chronic, of moderate severity

PATHOLOGICAL DISCUSSION

DR MALLORY Autopsy showed an extremely hypertrophied heart, the cause of which was an obviously stenotic aortic valve (Fig 1) It appeared to have only two cusps, both of which were mas-

Some difference of opinion was expressed regarding the mitral valve I thought that it was normal, without evidence of rheumatic heart disease The coronary arteries showed minimal atheromatosis The left ventricle was particularly hypertrophied (Fig 2), and the right ventricle was reduced to a rather narrow slit This suggested the possibility of a Bernheim syndrome, if one believes in such a thing, and I should like to raise that point for discussion To those not familiar with the hypothesis, Bernheim¹ suggested many years ago that in certain cases of massive dilatation or hypertrophy of the left ventricle, deviation of the septum into the right ventricle produced sufficient narrowing of the right ventricle so that it was unable to fill properly with blood and failure of the right side of the heart occurred secondary to left ventricular hypertrophy

Have you any comment, Dr Bland?

DR BLAND I have never recognized this syndrome clinically Once or twice a year someone from the

FIGURE 1 Photograph of the Aortic Valve

sively calcified, and there were great warty excrescences of calcium in the sinuses of Valsalva Each of these cusps appeared considerably larger than a normal cusp On one side I think that a ridge could be made out in the middle of the cusp, such as that seen in congenital fusion of the aortic valve It is my impression that a large proportion of these calcareous aortic stenoses develop on the basis of congenital bicuspid valves, and this case suggests that etiology

DR WALTER BAUER What do you mean by a large percentage — 20 or 80 per cent?

DR MALLORY Eighty per cent

Pathology Department presents us with a possible example post mortem It is an interesting concept It implies not exactly right-sided heart failure but rather an inability of the blood to get into the right ventricle In 1945, 3 cases that clinically fit in more or less with this concept were described² The patients were said to have had right-sided heart failure, swelling and edema, without previous pulmonary congestion (left-sided heart failure), and at post mortem the sections were similar to the one that Dr Mallory has just demonstrated

DR MALLORY Those who believe in the syndrome consider the diagnosis to require evidence of right-

ded heart failure before evidence of left-sided heart failure. In most published cases evidence of such a sequence is sketchy, as in the case under discussion. This man had paroxysmal dyspnea, probably due to left ventricular failure at an early stage in the symptoms.

DR. BLAND: I wonder if that concept need be true. It takes time for the left ventricle to encroach by hypertrophy or dilatation into the right ventricular cavity. May it not be failing at that time, whereas later on it actually obstructs the inflow into the right ventricle and the signs of right-sided heart failure intervene?

DR. MCGINN: This is an early age for occurrence and an unusual period for a patient with aortic

DR. MALLORY: No anatomic immediate cause of death was found. I think that one must assume that it was due to ventricular fibrillation.

CASE 33212

PRESENTATION OF CASE

A fifty-eight-year-old Polish mill worker entered the hospital because of hematuria.

Ten months before admission there had been a single episode of painless massive hematuria. Three months later hematuria began intermittently, and gradually became more frequent and severer so that by the week before entry the patient was passing "jelly-like" urine. No symptoms attended this bleeding until two days before admission, when there was mild left-flank discomfort.

The patient had had a chronic cough for years, but there was no history of tuberculosis or other major illness.

Physical examination disclosed persistent moist rales at both lung bases. The heart and abdomen were normal. There was no costovertebral-angle tenderness. Rectal examination revealed the prostate to be enlarged two and a half times normal, soft, smooth and symmetrical, and a sessile mass, about 3 cm. in diameter, was palpated high in the posterior rectal wall. A cystoscope was passed easily. There was a long, worm-like clot lying unattached in the floor of the bladder. The mucosa was normal, and the capacity 300 cc. The trigone and ureteral orifices looked normal. Clear urine was ejected from the right ureter, none from the left. There was mild hypoplasia of the median and lateral lobes of the prostate, the prostatic urethra appeared normal. Catheters were passed to 28 cm. on both sides, a slight obstruction being felt at 25 cm. on the left. Bloody fluid was aspirated from the left ureter, although there seemed to be no actual production of urine on that side. A smear of this fluid prepared according to the Papanicolaou technic showed tumor cells. Indigo-carmin appeared on the right two and a half minutes after injection, none was seen on the left.

The temperature was 99°F, the pulse 88, and the respirations 22. The blood pressure was 180 systolic, 100 diastolic.

Examination of the blood revealed a red-cell count of 4,650,000, with a hemoglobin of 85 per cent, and a white-cell count of 11,200. The urine had a specific gravity of 1.014 and gave a +++ test for albumin. Urine culture revealed no growth. The sediment contained innumerable red cells. The total protein, nonprotein nitrogen, carbon dioxide and chloride were normal.

FIGURE 2. Photograph of a Cross Section of the Heart

stenosis to survive in congestive failure unless explained by a damaged myocardium or by the Bernheim theory.

DR. MALLORY: The patient died at an early age for calcareous stenosis — fifteen years younger than the average.

DR. MCGINN: When congestive failure appears with aortic stenosis there is usually a downhill course over a period of seven or eight months. I believe that this case was complicated either by myocardial changes or by a Bernheim syndrome.

DR. BAUER: This case may have been the exception.

DR. MALLORY: Yes.

DR. MCGINN: In answer to the question about the mitral murmurs, it is possible for a dilated heart to give the findings of mitral stenosis with a typical murmur and thrill in the presence of a normal valve. It is interesting that in this case the maximal location of the aortic-valve murmur and thrill was in the third and fourth interspaces.

A PHYSICIAN: Have you seen any cases of the presystolic crescendo that turned out to have a normal mitral valve?

DR. MCGINN: I recall a case that seemed to be so typical that a valvulotomy was done.

A PHYSICIAN: What do you consider the cause of death in the case under discussion?

Mitral stenosis and regurgitation
 Cardiac hypertrophy
 Congestive failure, left and right ventricles

ANATOMICAL DIAGNOSES

Calcareous aortic stenosis

DR MALLORY Those who believe in the syndrome consider the diagnosis to require evidence of right-

DR TRACY B. MALLORY Dr Chute will you tell us the operative findings?

DR RICHARD CHUTE I helped Dr Rogers, the resident do the operation. The lesion turned out to be a papillary tumor of the kidney, which was removed by transperitoneal nephrectomy. The kidney was approximately normal in size. There was papillomatosis of the renal pelvis, which was much more marked in the upper pole than in the lower pole. The upper calyces were entirely filled with tumor, whereas in the lower ones there was a considerable amount of space that the retrograde dye could not enter.

DR COLBY What was the preoperative diagnosis?

DR CHUTE Tumor of the kidney.

A PHYSICIAN Was there any drop in blood pressure after operation?

DR MALLORY Nothing to suggest shock.

A PHYSICIAN Was not the diagnosis of tumor made on interpretation of the pyelogram?

DR COLBY I think that in this case we paid a good deal of attention to the tumor cells. Is that true, Dr Chute?

DR CHUTE The pyelogram offered one bit of contributory evidence but we were not swayed by that.

DR COLBY I was interested in Dr Dean's remark regarding Dr Papanicolaou's technic because we are now going through the throes of trying to evaluate the smear diagnosis of carcinoma in cases such as this. We are not yet certain about this test. In one case we got a positive report of tumor cells, and since there was a definite renal defect on x-ray examination, the kidney was removed, but no tumor was present anywhere in the kidney. That set us back on our heels a good deal. The disturbing thing was that the slide that contained the tumor cells was broken, so that we were unable to check it. We believe that the presence of tumor cells in the urine is not sufficient justification for removing a kidney. This test is still in the experimental stage, and we do not wish to decry the procedure on one unfortunate experience. Everyone, including the X-ray Department, thought that we were justified in operating on the patient regardless of the presence or absence of the tumor cells in the urine.

DR DEAN There are two conditions that we know of in which tumor-like cells can be found and one would not wish to remove the kidney. One is adenoma of an exceedingly low grade of malignancy. The other is ureteritis cystica. The cells from the surfaces of the small cysts look like those of a papilloma.

DR DAVID W. WILLIAMS In our experience in a series of 100 consecutive cases there were positive reports in 8, and 7 of these patients were proved to have tumors. One out of every 8 in other words, is an error.

DR MALLORY The same diagnostic problem of the value of smear diagnosis of cancer, of course, holds for cancer of the female genital tract and of the lung. There are cases in which it is impossible to obtain a biopsy specimen and in which smear examination has led to a positive diagnosis. For instance cancer of the fallopian tube has been correctly diagnosed on smear. In the lung it is not uncommon to have a tumor so far out in the periphery that it is impossible to reach it with a bronchoscope. We believe that a positive smear constitutes important evidence. We are still conservative, however, in accepting it without other support, and if there is any chance of confirming the diagnosis with biopsy of the old-fashioned sort, we always do it.

A PHYSICIAN How much better are aspiration biopsies than the Papanicolaou technic?

DR MALLORY That depends entirely on who takes the biopsy. There is in my experience about one surgeon in twenty who can take satisfactory aspiration biopsies. The rest are not worth looking at. It seems like a simple technic, but most people are not successful in providing anything on which I can make a diagnosis.

A PHYSICIAN Are the successful surgeons consistent?

DR MALLORY Yes, most of them have learned the technic elsewhere — in Stockholm or at the Memorial Hospital in New York.

CLINICAL DIAGNOSIS

Renal tumor

DR DEAN'S DIAGNOSIS

Tumor of upper pole of left kidney

ANATOMICAL DIAGNOSIS

Papillary carcinoma of left renal pelvis

PATHOLOGICAL DISCUSSION

DR MALLORY The real question came up in the later handling of this patient with a papillary tumor of the renal pelvis. One knows the possibility of recurrence of such a tumor, whether by implantation or not farther down in the ureter and sometimes in the bladder. This man had a simultaneous carcinoma of the rectum, and he eventually went through three operations.

DR COLBY One question that came up was whether it was advisable to remove the entire ureter, since the patient had another cancer.

DR MALLORY I think that the cancer of the rectum was far more important than the possibility of cancer of the ureter.

A PHYSICIAN It is easy to take out the stump of the ureter when the rectum is removed.

DR MALLORY I should think that would be the best procedure in such circumstances.

An intravenous pyelogram showed normal function on the right, but none on the left. A retrograde pyelogram demonstrated markedly dilated calyces in the lower portion of the left kidney, no calyces filled in the upper portion. The ureter was not outlined, but the ureteropelvic insertion appeared to be low. X-ray films of the skull and spine showed no evidence of tumor. Biopsy of the rectal mass showed adenocarcinoma.

A renal operation was performed on the sixth hospital day.

DIFFERENTIAL DIAGNOSIS

DR ARCHIE L. DEAN* The history suggests organic disease somewhere in the genitourinary organs, and the painless massive hematuria suggests that it came from one of the kidneys. "Massive" seems to be the term to use in this case. I think that the term "total hematuria" is a good one too, indicating that the blood is diffused equally throughout all the urine, in contradistinction to initial or terminal hematuria. That is one of the characteristics of bleeding from the kidney. It should be emphasized that the hematuria, no matter what the cause, was always intermittent in this case.

I assume that the sessile mass in the wall of the rectum represented a carcinoma of the rectum.

"There was a long, worm-like clot lying unattached in the floor of the bladder." That also helps to localize the source of the bleeding in one of the kidneys, because not infrequently if the kidney bleeding is sufficiently severe so that clots form, a perfect cast of the ureter is passed.

"Clear urine was ejected from the right ureter, none from the left." This was at a time of bleeding so that we are assisted to a certain extent in localizing this hemorrhage in the left kidney or ureter.

After referring several hundreds of specimens to Dr. Papanicolaou while he was developing his technic, I can state that a definitely positive diagnosis is of considerable clinical significance. By the use of this technic, however, one would not expect to be able to differentiate a tumor of the renal pelvis from a tumor of the renal parenchyma that had ulcerated into the pelvis.

"Indigo-carmin appeared on the right two and a half minutes after injection, none was seen on the left." That may or may not have significance in relation to the hypertension, on the basis of obstruction of the vascular system of the left kidney.

The x-ray appearance could have been due to a tumor of the parenchyma, with obliteration of the upper calyces. It could also have been caused by tumor of the pelvis. It is less likely that it was due merely to a clot.

The ureter was not outlined, but the ureteropelvic insertion appeared to be low — there may be significance in this, but I do not believe that

There is no mention of a film of the chest, I should like to see one.

Biopsy of the rectal mass showed adenocarcinoma. Since the most frequent type of tumor of the renal parenchyma is an adenocarcinoma, one wonders if there was an association. I think that such an association is extremely rare, although multiple tumors are quite common. But either a primary adenocarcinoma of the kidney giving rise to metastases in the rectum or a rectal tumor involving the kidney is too rare to be considered seriously.

DR LAURENCE L. ROBBINS A film of the chest was taken, and so far as I can see, the chest is entirely normal. There is no evidence of tumor. The changes in the heart and aorta are what one would expect in a man of this age. The lungs are essentially clear.

The pyelograms are essentially as described in the protocol. In the intravenous pyelogram there is no evidence of function on the left side over a relatively limited period. The right urinary passages are, so far as I can see, normal. This is a film of a retrograde pyelogram. On the left side we see filling of the inferior calyces, which are dilated, with some irregularity along this area. The ureteropelvic insertion appears to be lower than is usual. At no time do we see a good kidney outline, other than the lower pole, on the left side. This film suggests that the upper pole is somewhat widened at this point, but I do not believe that the film is sufficiently detailed to be certain.

DR DEAN This appears to be a pyelogram of a tumor of the upper pole of the kidney, obliterating the upper calyces.

A PHYSICIAN Could it not be a double kidney?

DR DEAN It could be, although it does not look just right for that.

Another point is that there is usually some degree of function in a kidney that has a tumor limited to the upper pole. The lack of function is something that I have not been able to understand. I am uncertain because the picture is not clear cut. But on the basis of the findings, the best I can suggest is a tumor of the upper pole of the left kidney.

A PHYSICIAN I should like to ask if Dr. Robbins can recognize the outline of a mass on the left. From where I sit I can see a definite shadow.

DR ROBBINS So far as I can tell the mass to which you refer is produced simply by the colon swinging around in this manner. This other mass, of course, is fluid in the fundus of the stomach, which disappears as soon as the patient is turned over on the abdomen, when it is replaced with air. The thing that is bothersome is that it is not possible to see a definite mass in the region of the upper pole of the kidney.

A PHYSICIAN Do we have any information about the differential count? The white-cell count was 11,200, but no differential is given.

DR FLETCHER H. COLBY It was normal.

BAULEY

result from environmental circumstances — from better standards of living and, in particular, from better nutrition

The converse has been seen in war-stricken countries, where mass malnutrition, amounting in places to mass starvation, has seriously stunted the growth of a generation of children. It is in an attempt to evaluate the factors involved that Talbot and his associates have made the studies reported elsewhere in this issue of the *Journal*.

These investigators found that, of a group of over a hundred abnormally short children from two and a half to fifteen years of age, 51 per cent showed no physical disturbance and no hereditary factor to account for the stuntedness. The majority of the patients had presented difficult feeding problems for most of their lives, although the average protein intake, if properly assimilated, was considered to be adequate in all for normal growth. The conclusion was reached that the caloric intake in these cases was more important than the protein itself, because in the absence of sufficient calories from other foods, the protein intake and probably some part of the body protein as well were called on to produce energy.

Attempts to improve the situation by an increased diet were usually unrewarded by any co-operative response on the part of the patients, and further analysis of the group showed that in the majority one or more of certain untoward factors were present. These consisted of mental deficiency or an emotional reaction to poor environmental factors on the part of the patients, of poor family economic situations and of emotional instability, delinquency or psychosis on the part of the mothers.

Correction of the emotional difficulties usually resulted in improved appetite and a gain in weight, but not always in a resumption of growth.

The conclusions may be drawn that growth failure is the indirect result only of malnutrition and that it follows directly from a lack of pituitary growth hormone, this lack being due to the poor nutrition. Such conclusions are strengthened by the fact that improved growth may not result from the acceptance of an adequate diet but does result when methyl testosterone is added to the diet.

MASSACHUSETTS MEDICAL SOCIETY

DEATH

TIGHE — Michael A. Tighe, M.D., of Lowell, died April 8. He was in his sixty-sixth year.

Dr. Tighe received his degree from Harvard Medical School in 1908. He was formerly president of the Middlesex North District Medical Society, and was secretary of the Massachusetts Medical Society. He was a fellow of the American College of Surgeons, New England Obstetrical and Gynecological Society, and American Medical Association.

He is survived by his widow, three sons, a daughter, five grandchildren and two sisters.

MISCELLANY

METOPON HYDROCHLORIDE

In 1929, with the funds provided by the Rockefeller Foundation, the National Research Council, through the Committee on Drug Addiction, undertook a co-ordinated program to study drug addiction and search for a nonaddicting analgesic comparable to morphine. The principal participating organizations were the University of Virginia, the University of Michigan, the United States Public Health Service, the Treasury Department's Bureau of Narcotics and the Massachusetts Department of Public Health, which brought together chemical, pharmacologic and clinical facilities for the purpose of the study. Metopon (methyl dihydromorphine hydrochloride) is one of the many compounds made and studied in this co-ordinated effort.

Metopon is a morphine derivative. Pharmacologically, it is qualitatively like morphine even to the properties of tolerance and addiction liability. Chemically, Metopon differs from morphine in three particulars — one double bond of the phenanthrene nucleus has been reduced by hydrogenation, the alcoholic hydroxyl has been replaced by oxygen and a new substituent, a methyl group, has been attached to the phenanthrene nucleus. Studies made thus far indicate that, pharmacologically, Metopon differs from morphine quantitatively in all its important actions — its analgesic effectiveness is at least double and its duration of action is about equal to that of morphine, it is nearly devoid of emetic action, tolerance to it appears to develop more slowly and to disappear more quickly and physical dependence builds up more slowly than with morphine, therapeutic analgesic doses produce little or no respiratory depression and much less mental dullness than do those of morphine, and it is relatively effective by oral administration.

In addition to animal experiments these differences have been established by extensive employment of the drug in two types of patients — those addicted to morphine and others, such as patients in the terminal stages of cancer, needing prolonged pain relief but without previous opiate experience. In morphine addicts, Metopon appears only partially to prevent the impending signs of physical and psychological dependence. In terminal cancer, administered orally, it gives adequate pain relief with little mental dulling, without nausea or vomiting and with slow development of tolerance and dependence. The latter properties place Metopon in a class by itself for the treatment of the chronic suffering of cancer, and it is for that purpose exclusively that it is being manufactured and marketed.

The capsules are put up in bottles of 100, and each capsule contains 50 mg. of Metopon hydrochloride. They can be obtained by physicians only from Sharp and Dohme or Parke, Davis and Company, on a regular official narcotic order form, which must be accompanied by a signed statement supplying information concerning the number of patients to be treated and the diagnosis on each. The drug will be distributed only for the purpose of oral administration for the relief of chronic pain in cancer cases.

The dose of Metopon hydrochloride is 60 to 90 mg. (two or three capsules) to be repeated only on recurrence of pain, avoiding regular by-the-clock administration. As with morphine, it is most desirable to keep the dose at the lowest level compatible with adequate relief of pain. Therefore, administration should be started with two capsules per dose, increasing to three only if the analgesic effect is insufficient.

NEW YORK ACADEMY OF MEDICINE

THE autumn that saw the first public demonstration of ether as an anesthetic also witnessed another event less spectacular in its nature and less far-reaching in its influence, but still of continuing importance to the progress of medicine. This event was the annual meeting, at Peletier's Restaurant, on Broadway, New York City, of the Society for the Relief of Widows and Orphans of Medical Men. The importance of this particular meeting, a century ago, was that from it came the preliminary plans for the establishment of the New York Academy of Medicine.

The original function of the Academy, according to its story as told by Dr. Howard A. Rusk, in the March 9 issue of the *New York Times*, was "to promote the honor, dignity, the respectability and the usefulness of the medical profession." That

function has not changed, and the distinction with which it has been discharged has increased as the years have rolled on, even until this, the year when its centennial celebration has recently been observed.

Important among the various functions of the Academy has been the maintenance of its library, coeval with the Academy itself, and now numbering 225,000 volumes, a library second in size only to the Army Medical Library in Washington. The Academy has also put on foot various studies contributing to the public health and to the practice of medicine, under its auspices are conducted public lectures on health and disease, similar to those sponsored in this city by the Harvard Medical School.

Various associations brought deliberately into being for the unselfish motive of improving the welfare of mankind have had long and inspiring histories. Such organizations have been the English and Scottish Royal Colleges of Physicians and Surgeons, dating back to the sixteenth century, and their American counterparts, as well as the Royal Society of London — the "Invisible College" — that rose, with others, in the seventeenth century. There have been many such associations, first and last, for the promotion of science in general and a better understanding of disease in particular, for "where there is love of man there is love of the art."

There is, curiously, no similar organization in New England, although the various functions of an academy are adequately carried on by the state medical societies, the medical schools and, notably, the Boston Medical Library, fellowship in which carries with it a dignity and an intellectual prestige that still have their value.

MALNUTRITION AND GROWTH

CERTAIN phenomena that have been observed in relation to growth in the human species deserve our attention. In a matter of generations, stature and general development have improved to a degree that can almost be measured in inches. This change is so general and has been so rapid that it cannot be attributed to any evolutionary deviation, heredity may play a part in it, but it must in the main

result from environmental circumstances — from better standards of living and, in particular, from better nutrition

The converse has been seen in war-stricken countries, where mass malnutrition, amounting in places to mass starvation, has seriously stunted the growth of a generation of children. It is in an attempt to evaluate the factors involved that Talbot and his associates have made the studies reported elsewhere in this issue of the *Journal*.

These investigators found that, of a group of over a hundred abnormally short children from two and a half to fifteen years of age, 51 per cent showed no physical disturbance and no hereditary factor to account for the stuntedness. The majority of the patients had presented difficult feeding problems for most of their lives, although the average protein intake, if properly assimilated, was considered to be adequate in all for normal growth. The conclusion was reached that the caloric intake in these cases was more important than the protein itself, because in the absence of sufficient calories from other foods, the protein intake and probably some part of the body protein as well were called on to produce energy.

Attempts to improve the situation by an increased diet were usually unrewarded by any co-operative response on the part of the patients and further analysis of the group showed that in the majority one or more of certain untoward factors were present. These consisted of mental deficiency or an emotional reaction to poor environmental factors on the part of the patients, of poor family economic situations and of emotional instability, delinquency or psychosis on the part of the mothers.

Correction of the emotional difficulties usually resulted in improved appetite and a gain in weight, but not always in a resumption of growth.

The conclusions may be drawn that growth failure is the indirect result only of malnutrition and that it follows directly from a lack of pituitary growth hormone, this lack being due to the poor nutrition. Such conclusions are strengthened by the fact that improved growth may not result from the acceptance of an adequate diet but does result when methyl testosterone is added to the diet.

Dr. Tighe received his degree from Harvard Medical School in 1908. He was formerly president of the Middlesex North District Medical Society, and was secretary of the Massachusetts Medical Society. He was a fellow of the American College of Surgeons, New England Obstetrical and Gynecological Society and American Medical Association.

He is survived by his widow, three sons, a daughter, five grandchildren and two sisters.

MISCELLANY

METOPON HYDROCHLORIDE

In 1929, with the funds provided by the Rockefeller Foundation, the National Research Council, through the Committee on Drug Addiction, undertook a co-ordinated program to study drug addiction and search for a nonaddicting analgesic comparable to morphine. The principal participating organizations were the University of Virginia, the University of Michigan, the United States Public Health Service, the Treasury Department's Bureau of Narcotics and the Massachusetts Department of Public Health, which brought together chemical, pharmacologic and clinical facilities for the purpose of the study. Metopon (methyldihydromorphine hydrochloride) is one of the many compounds made and studied in this co-ordinated effort.

Metopon is a morphine derivative. Pharmacologically, it is qualitatively like morphine even to the properties of tolerance and addiction liability. Chemically, Metopon differs from morphine in three particulars — one double bond of the phenanthrene nucleus has been reduced by hydrogenation, the alcoholic hydroxyl has been replaced by oxygen and a new substituent, a methyl group, has been attached to the phenanthrene nucleus. Studies made thus far indicate that, pharmacologically, Metopon differs from morphine quantitatively in all its important actions — its analgesic effectiveness is at least double and its duration of action is about equal to that of morphine, it is nearly devoid of emetic action, tolerance to it appears to develop more slowly and to disappear more quickly and physical dependence builds up more slowly than with morphine, therapeutic analgesic doses produce little or no respiratory depression and much less mental dullness than do those of morphine, and it is relatively effective by oral administration.

In addition to animal experiments these differences have been established by extensive employment of the drug in two types of patients — those addicted to morphine and others, such as patients in the terminal stages of cancer, needing prolonged pain relief but without previous opiate experience. In morphine addicts, Metopon appears only partially to prevent the impending signs of physical and psychical dependence. In terminal cancer, administered orally, it gives adequate pain relief with little mental dulling, without nausea or vomiting and with slow development of tolerance and dependence. The latter properties place Metopon in a class by itself for the treatment of the chronic suffering of cancer, and it is for that purpose exclusively that it is being manufactured and marketed.

The capsules are put up in bottles of 100, and each capsule contains 50 mg. of Metopon hydrochloride. They can be obtained by physicians only from Sharp and Dohme or Parke, Davis and Company, on a regular official narcotic order form, which must be accompanied by a signed statement supplying information concerning the number of patients to be treated and the diagnosis on each. The drug will be distributed only for the purpose of oral administration for the relief of chronic pain in cancer cases.

The dose of Metopon hydrochloride is 60 to 90 mg. (two or three capsules), to be repeated only on recurrence of pain, avoiding regular by-the-clock administration. As with morphine, it is most desirable to keep the dose at the lowest level compatible with adequate relief of pain. Therefore, administration should be started with two capsules per dose, increasing to three only if the analgesic effect is insufficient.

Tolerance to any narcotic drug develops more rapidly with excessive dosage and under regular by-the-clock administration. Also as a rule, the pain of cancer varies widely in intensity from time to time. Pain, therefore, should be the only guide to the time of administration and the dosage level. Tolerance to Metopon hydrochloride develops slowly. It can be delayed or interrupted entirely by withholding the drug occasionally for twelve hours or for as much of that period as the incidence of pain will permit.

To each physician will be sent a record card for each patient to whom Metopon hydrochloride is to be administered. He will be requested to fill out these cards and to return them in the addressed return envelope. He must furnish this record of his patient and his use of Metopon hydrochloride if he wishes to repeat his order of the drug. The principal object of this detailed report is to check the satisfactoriness of the use of Metopon hydrochloride in general practice. The physician's co-operation in making it as complete as possible is earnestly solicited.

The limited use of Metopon hydrochloride as described above has been recommended by the Committee on Drug Addiction, National Research Council, and the committee, with the co-operation of the American Cancer Society, will supervise the distribution of the drug. The committee is composed of Dr. William Charles White, chairman, Washington, D. C., H. J. Anslinger, Commissioner of Narcotics, United States Treasury Department, Washington, D. C., Lyndon F. Small, National Institute of Health, Washington, D. C., and Dr. Nathan B. Eddy, National Institute of Health, Washington, D. C. Queries and comments on Metopon may be directed to Dr. Eddy, who will answer them for the committee.

CORRESPONDENCE

BASIS OF STUDENT HEALTH SERVICES

To the Editor: In view of the fact that there has been in the past and will be in the future considerable discussion between the relative advantages of a compulsory health-insurance plan and the development of medical-care programs on a voluntary prepaid basis, I think that the editorial "The Third National Conference on Health in Colleges" in the April 19 issue of the *Journal of the American Medical Association* is of interest. This editorial speaks of the organization of student health services on the basis of voluntary prepaid medical-care and hospital insurance. It is common knowledge, however, that at the present time many educational institutions, such as Harvard University, have a well organized medical-care program on a compulsory health-insurance basis. I am wondering whether the writer of the editorial would like to scrap the program that has been so successful at Harvard, replacing it with a voluntary insurance program.

BOOK REVIEWS

Pneumoperitoneum Treatment. By Andrew L. Banyai, M.D. 8°, cloth, 376 pp., with 74 illustrations and 16 tables. St. Louis: C. V. Mosby Company, 1946. \$6.50.

This book represents a compilation of practically all the literature on the subject of artificial pneumoperitoneum therapy, as well as an evaluation by the author, who has had extensive personal experience as a pioneer in this field. The book does not confine itself to pneumoperitoneum therapy in the narrow sense. It embraces the entire gamut of phthisiotherapy, as well as the many allied chest conditions, and appraises the place of this treatment in the entire scheme of general treatment. The physiology and the physiologic pathology of various chest and abdominal conditions, both tuberculous and nontuberculous, are well considered.

Although artificial pneumoperitoneum therapy is primarily employed in pulmonary tuberculosis, the author also discusses its use in such conditions as pulmonary abscess, bronchial asthma, bronchiectasis and pulmonary emphysema. In addition, he considers its role in abdominal adhesions, ulcerative colitis, intestinal and gastric bleeding and so forth. As yet, however, this form of therapy has not found the universal favor that artificial pneumothorax or thoracoplasty has. The adherents are vehement in their praise, but the greater portion of workers in the field of pulmonary tuberculosis have been lukewarm in their acceptance or have rejected the therapy entirely. This is easily explained by the chronicity, the protean nature and the many forms that such a disease as tuberculosis assumes. Nevertheless, regardless of the merits of artificial pneumoperitoneum therapy, the author has brought the extensive literature of the past ten to fifteen years up to date and has given the profession the benefit of his long and rich experience in this field. Whether this treatment is employed extensively or only occasionally, the book affords a ready reference and intelligent discussion of the many phases pertaining to the subject.

It is for this reason that the book should be read by all men interested in diseases of the chest. It should also find a place on the shelves of all medical libraries as a source of authoritative information.

Mother and Baby Care in Pictures. By Louise Zabriskie, R.N. Third edition, modernized. 8° cloth, 203 pp., with 229 illustrations and 7 tables. Philadelphia: J. B. Lippincott Company, 1946. \$2.00.

This new edition of a manual for mothers has been revised, and many additions and changes have been made in the text. Emphasis is placed on nutrition and the care of the baby. The mechanism of labor and the management of delivery in the hospital and the home are explained in great detail. The immediate care of the baby has been brought up to date, and the material on general care, habits and development during the first year has been entirely reorganized. The text is well organized and excellently illustrated. The plate on the male anatomy is superfluous and not pertinent and could have been omitted without detracting from the value of the book. The ring type of binding is not suitable for hard usage in the home. This manual should prove of value to all mothers and especially to expectant mothers.

Narco-Analysis: A new technique in short-cut psychotherapy. A comparison with other methods. And notes on the barbiturates. By J. Stephen Horsley. 12° cloth, 134 pp. New York and London: Oxford University Press, 1943. \$2.50.

This is the first American edition of this book, which was originally published in England in 1943. It concerns the technique and use of narcoanalysis in psychiatric illness. The author states that the theory of narcoanalysis involves both biochemical and psychodynamic concepts, the former being that persons who for a variety of reasons are sullen, reticent, inhibited or even mute may, during narcosis, converse spontaneously revealing anxiety conflicts or painful memories from which either consciously or unconsciously they seek refuge, whereas the latter incorporates the generally accepted views of conflict repression and amnesia with reference to their modification by hypnosis and analysis.

One chapter is devoted to a discussion of the barbiturates used in psychiatry, and the writer points out that since the number of barbiturates is increasing, he believes that personal

familiants with all forms is impossible, and he recommends a number that in his experience have proved successful.

The use of barbiturates is divided into three therapeutic classes: simple hypnotics, those providing a means of producing prolonged narcosis, and those affording a means of establishing contacts with previously reticent or inaccessible patients. In addition the chapter lists certain conditions that require special caution in their use. Old-age nephritis, liver disease, advanced cardiovascular disease, any tendency to respiratory spasm and toxemias are contraindications to the use of barbiturates.

The rationale of the procedure is explained by the statement that "narcosis is produced very slowly by the gradual administration of a suitable drug and during the stage of light narcosis, a true hypnotic state is induced by verbal suggestion, and the patient is then amenable to psychological analysis and synthesis." Under the influence of the barbiturates, because of the removal of inhibitions the latent or repressed conflict comes to the surface, and in a brief period the physician obtains information relevant to the patient's mental state that he could not have obtained in a month by ordinary means.

Following this the psychiatrist determines the salient factors responsible for the condition of the patient as well as the making of new associations to restore a normal attitude to reality. Two main indications are given for the use of narcoanalysis to overcome resistance and, in cases due to recent stress as a quick discovery of the principal emotional upset.

One chapter is devoted to a discussion of the employment of narcoanalysis in wartime. Two interesting reports are included on its use in the British Army and the Royal Navy. The chapters on abreaction and transference are instructive although the case reports are necessarily brief because of the small size of the book.

The author has presented his material in a clear and concise manner, the bibliography is extensive. The book is recommended as a valuable addition to the psychiatrist's library.

Sex, Marriage and Family. By Thurman B. Rice, M.D. 8th cloth, 272 pp. Philadelphia: J. B. Lippincott Company, 1946. \$2.50.

The author discusses in detail every aspect of marriage, from the basic sexual relation through all the conditions of married life, including psychological and economic factors and the physical, mental and emotional changes incidental to the change in family status, children and "in-laws." A special chapter is devoted to the problems of marriage in wartime, with emphasis on the status of the returned serviceman. The text is written in a bold, frank manner with a trace of flippancy, but on the whole, the proffered advice is sound and practical and should prove of value to interested persons of both sexes. It is to be deplored that the word "sex" is used as a synonym for sexual relation rather than in its correct sense.

Autopsy, Diagnosis and Technique. By Otto Saphir, M.D. With a foreword by Ludwig Hektoen, M.D. Second edition revised and enlarged. 12th, cloth, 405 pp., with 69 illustrations. New York: Paul B. Hoeber, Incorporated, 1946. \$5.00.

This practical manual of autopsy technique first published in 1937, has been enlarged by the addition of new material. The discussion of diseases of the breast has been greatly expanded in the interest of the general practitioner and student since the incidence of breast lesions is high, and there is a vital need of examining this region. New material has been added on accidental death, conditions peculiar to stillborn and newborn infants, nose and accessory sinuses, vitamin deficiencies and certain tropical diseases. Emphasis is placed on anatomically demonstrable lesions. The manual gives merely a diagnostic outline of the gross lesions generally found in structures and organs. Histopathologic lesions are not considered. Only one method of autopsy technique—a modified Robitansky procedure—is described.

The manual, which is written primarily for the student laboratory assistant and general practitioner, is well organized and should prove valuable to those interested in gross pathology.

Penicillin: Its practical application. Under the general editorship of Sir Alexander Fleming, M.B., B.S., F.R.C.P., F.R.C.S., F.R.S. 8th cloth, 50 pp., with 59 illustrations. Philadelphia: Blakiston Company, 1946. \$7.00.

The development of penicillin marks a dramatic episode in medical history.

It is appropriate that Sir Alexander Fleming, the discoverer, was invited by the Blakiston Company to edit "a series of independent contributions giving each author's views on the use of penicillin therapy in a disease or in infections of some region of the body" and that the collaborators he selected to take part in this undertaking were his English colleagues whose efforts combined to make the new antibiotic available for clinical use as promptly as possible.

The book is as British as John Bull. It was written by British authors and first printed in Great Britain and emphasizes the work on penicillin in England, although it by no means slight that of American investigators. And as is so often true in English medical books, the literary style of each chapter is uniformly excellent.

A delightful account is given of penicillin's discovery, its chemistry, manufacture, pharmacology and clinical use. The illustrations are interesting and indeed of historical importance since a picture is reproduced of the original culture plate on which the action of penicillin was observed. At the end of each chapter is a useful list of references leading to more detailed study of the subject under discussion. By way of conclusion, there is an admirable index.

On the whole, this is a noteworthy contribution that is almost faultless. The first printing of the first edition bids fair to rank as a medical classic. Any student or physician can read the monograph with benefit. It offers a restrained account of a most significant medical development, it gives sound advice regarding the proper management of many different clinical conditions, and it is a model of medical literature.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

X-Rays and Radium in the Treatment of Diseases of the Skin. By George M. MacKee, M.D., professor of clinical dermatology and director of Department of Dermatology (Skin and Cancer Unit), New York Post-Graduate Medical School and Hospital, Columbia University, and Anthony C. Cipollaro, M.D., assistant professor of dermatology and assistant director of Department of Dermatology (Skin and Cancer Unit), New York Post-Graduate Medical School and Hospital, Columbia University. With a contribution by Hamilton Montgomery, M.D., associate professor of dermatology, Mayo Foundation for Medical Education and Research, Graduate School, University of Minnesota. Fourth edition thoroughly revised. 8th cloth, 665 pp., with 321 illustrations. Philadelphia: Lea and Febiger, 1946. \$10.00.

Dr. MacKee and his collaborators have thoroughly revised this fourth edition of a standard work, first published in 1921 and revised from time to time. The authors have attempted to correlate the special knowledge of the dermatologist and the radiologist and to include the essential elements of physics and biology and seem to have succeeded in their objective. The first two chapters are devoted to a short and concise history of roentgen rays and radioactive elements. These are followed by chapters on physics and technique and finally on radiation of the skin in general and on the various diseases of the skin and tumors amenable to radiation therapy. The last chapter is on the medicolegal aspects of roentgen and radium therapy. A selective bibliography is appended to each chapter and a good index concludes the volume. The book is well printed in every way and a credit to the publisher. The work is recommended for all medical libraries and to physicians and others interested in the subject.

Progress in Neurology and Psychiatry An annual review Edited by E. A. Spiegel, M.D., professor and head of the Department of Experimental Neurology, Temple University School of Medicine 8°, cloth, 708 pp New York Grune and Stratton, 1946 \$8 00

This volume begins a new series of annual reviews in the fields of neurology and psychiatry in all their aspects. It is based primarily on the literature covering the period from December, 1944, to December, 1945. There are thirty-nine articles on pertinent subjects by recognized authorities and to each article is appended a complete list of references for the period covered. As an example, the review on pharmacology of the nervous system has a bibliography of seven hundred and twenty-eight articles. The objective of the work is to provide critical surveys of basic theoretical foundations, as well as the various clinical aspects of neurology and psychiatry. The book is well printed on a good soft paper. A slightly bolder type, however, would make for easier reading. The volume and its continuations are recommended for all medical libraries and should prove useful to all specialists in its fields.

Medical Services by Government Local, state and federal By Bernhard J. Stern, Ph.D., lecturer in sociology, Columbia University. A publication comprising studies of the Committee on Medicine and the Changing Order of the New York Academy of Medicine 8°, cloth, 208 pp New York The Commonwealth Fund, 1946 \$1 50

The author in this monograph furnishes an inventory, in historical perspective, of medical services now being provided directly and indirectly by government agencies on all levels—local, state and federal. The term "medical services" is understood to include all diagnostic and therapeutic, general and specialized services given to patients at home, in a doctor's office or at clinics, hospitals, schools or other institutions. It does not include community preventive measures, such as health education, sanitation, sewerage and water supply. The author has tried to indicate the pattern, scope, trends and nature of the medical services now being given and financed by all governmental agencies, and has succeeded in attaining his objective. The material is well arranged, well written and well published. This volume, as well as all others in the series, is recommended for medical, public-health and social libraries.

Allergy By Ench Urbach, M.D., chief, Allergy Department, Jewish Hospital, Philadelphia, and associate in dermatology, University of Pennsylvania School of Medicine, and Philip M. Gottlieb, M.D., associate, Allergy Department, Jewish Hospital, Philadelphia, and instructor in medicine, University of Pennsylvania School of Medicine. Second edition 4°, cloth, 968 pp, with 412 illustrations and 64 tables New York Grune and Stratton, 1946 \$12 00

The first edition of this treatise was published in 1943, and it has been found necessary to revise this second edition. Nearly 1300 new references have been inserted in the text, and the material has been increased by more than 10 per cent. Twenty-one new illustrations have been included. The following new sections have been added: Rh factor, allergic bronchitis and cough, eosinophilic erythredema and the psychosomatic aspects of allergy. Many sections have been materially enlarged. An appendix comprising a complete list of the concentrations used in patch testing has been added to the text. A double-column format has been used to cut down the bulkiness of the volume. The text is well printed with a good type on heavy coated paper. The weight of the volume could have been reduced by the use of a lighter uncoated paper. This treatise should be in all reference collections in medical libraries.

Allergy in Practice By Samuel M. Feinberg, M.D., associate professor of medicine and chief, Division of Allergy, Northwestern University Medical School. With the collaboration of Oren C. Durham, chief botanist, Abbott Laboratories, and Carl A. Dragstedt, Ph.D., M.D., professor and chairman, Department of Pharmacology, Northwestern University Medical School. Second edition 8°, cloth, 838 pp, with 34 figures and 25 tables Chicago Year Book Publishers, Incorporated, 1946 \$10 50

This standard textbook has been revised in the light of recent advances in the subject since the publication of the

first edition in 1944. The chapter on pollens and pollen allergy has been brought up to date, and pollen counts have been interpreted in the light of the newest survey methods. These new procedures in pollen counting are published for the first time. New material includes discussions on periarthritis nodosa, rheumatic fever, acute disseminated lupus erythematosus and the status of histamine and histamine antagonists in allergy. The text is well printed with a good readable type on good paper. An extensive bibliography is appended to each chapter. The volume is recommended for all medical libraries and should prove valuable to physicians interested in the subject.

NOTICES

NEW ENGLAND HEALTH INSTITUTE

The first meeting of the New England Health Institute since the war will be held at the University of New Hampshire, Durham, on June 16, 17 and 18. Train service from Boston to Durham is available about every two hours.

The program will include symposiums on public-health administration, health problems in welfare and genetics, industrial health and hygiene, vital statistics, maternal and child health, public-health nursing, communicable diseases, tuberculous control and school health and health education.

Since a large attendance is expected, all who plan to participate are urged to register early. Further information regarding the Institute will be furnished on application to the Executive Committee, New Hampshire State Health Department, Concord.

NEW ENGLAND PEDIATRIC SOCIETY

A meeting of the New England Pediatric Society will be held on Wednesday, May 28.

PROGRAM

1 15 p.m. Luncheon Vanderbilt Hall, Harvard Medical School (price, 70 cents)

3 00 p.m. Clinical Presentation of Dental Patients and Dental Subjects Paul K. Losch, D.M.D. Main Amphitheater, Children's Hospital

Members of the medical profession and students are cordially invited to attend.

5 30 p.m. Refreshments Longwood Towers

6 30 p.m. Dinner Longwood Towers (price, including tax, \$2 50) For members and friends

7 30 p.m. Child Health in Britain Dr. Alan Montreiff, Nuffield Professor of Child Health, University of London, physician, Hospital for Sick Children, Great Ormond Street, London

Members of the medical profession and students are cordially invited to attend.

SOCIETY MEETINGS AND CONFERENCES

ORAL ADMINISTRATION OF PENICILLIN*

Its Use in One Hundred and Fifty Cases

SIDNEY ROSS, M.D.,† FREDERIC G. BURKE, M.D.,‡ AND SIDNEY OLANSKY, M.D.§

WASHINGTON, D. C.

THE role of penicillin administered by mouth has been reported on by several investigators,¹⁻⁴ and the conclusion seems warranted that if the drug is given in sufficiently large doses, cures may be expected in susceptible infections. The optimal dose, as well as the necessity of preliminary or concurrent neutralization of the gastric acidity to avoid the inactivating influence of hydrochloric acid in the stomach when penicillin is administered orally, has been the subject of some controversy in the recent literature.⁵⁻⁷ To evaluate the latter point, penicillin blood levels were determined in a control group of over 600 subjects, plain calcium penicillin tablets containing a binding substance but without incorporated antacid, calcium penicillin tablets containing calcium carbonate, sodium citrate incorporated as buffers and plain calcium penicillin tablets with simultaneous administration of benzoic acid being used; the last combination was based on a report that benzoic acid is conjugated with glycine to produce para-aminohippuric acid and in this form competes with penicillin for excretion in the urine, thus prolonging and increasing the blood penicillin concentrations.⁸

The resulting penicillin blood levels at different intervals following the administration of these various preparations, details of which are presented more fully below, indicated that incorporation of a buffer such as calcium carbonate or sodium citrate in commercial penicillin tablets does not represent a necessary adjunct to oral penicillin therapy and that the blood levels obtained are not materially affected when these antacids are omitted. This is in keeping with the conclusion of McDermott et al.⁹ that penicillin preparations based solely on protection from acid destruction are not superior to

penicillin alone. Similarly, benzoic acid did not produce an increase or prolongation of the blood level when administered simultaneously with oral penicillin. Another point emphasized by this study was the noticeable variation in the blood levels achieved with the same oral dose of penicillin in different subjects, there also was considerable variation in the blood concentrations in the same subject from time to time when the same oral dose was employed. The penicillin titer in a given person was thus found to be somewhat unpredictable after oral administration. When the dose of oral penicillin was doubled or quadrupled, a comparable increase in the blood level did not result.

In the present series penicillin was administered orally in a total of 150 cases, including gonorrhea, subacute bacterial endocarditis, pneumonia, syphilis, cellulitis, impetigo and streptococcal pharyngotonsillitis. There were 76 children and 74 adults. Plain calcium penicillin tablets|| (without incorporated antacid) containing 25,000 units were employed in the treatment of 130 cases, and in 5 cases, tablets buffered with sodium citrate|| were used. In the other 15 cases a double gelatin capsule containing 100,000 units of penicillin was administered.

CLINICAL RESULTS

Gonorrhea

A total of 96 patients with gonorrhea were treated with penicillin by mouth. Of these, 63 were adults and 33 were children ranging in age from three to nine years (Table 1). In the adult group an arbitrary dosage schedule of 50,000 units of penicillin was administered every three hours for six doses, or a total of 300,000 units. The duration of therapy between the first and last dose was thus fifteen hours. The diagnosis was established prior to the institution of therapy by the demonstration of the organism on culture as well as on smear. Of the 63 cases treated, 57 were cured, and 5 were failures, a patient who had had negative cultures following

therapy returned a month later with a recurrence of the urethral discharge. He had had several sexual exposures during this hiatus, and this recurrence probably represented a reinfection rather than a relapse. Among the 51 men in the group there was only one failure, whereas among the 12 women there were 4 failures, 2 of which occurred in pregnant women.

Of the 33 children all were girls except one. The total dosage employed ranged between 200,000 and 500,000 units, the majority (24 patients) receiving

carditis with penicillin administered orally when the organism was relatively sensitive. The case summary is as follows:

M P, an 11-year-old girl, was seen on April 4, 1945, when a diagnosis of interventricular septal defect and probable subacute bacterial endocarditis was made. She was admitted to the hospital on the same day.

A heart murmur had first been noted when the patient was 1½ months old. Cyanosis and dyspnea had not been present at any time. Development had been normal, and the past history was essentially irrelevant. Four weeks prior to admission she complained of easy fatigability and

TABLE 1 Results of Oral Administration of Penicillin in the Treatment of Gonorrhea

TYPE OF DISEASE	FORM OF DRUG	TOTAL DOSAGE	DURATION OF THERAPY	CURES	FAILURES	POSSIBLE REINFECTIONS
		<i>Oxford units</i>	<i>hr</i>

Totals				83	11	2

either 300,000 or 400,000 units. There were failures in 5 cases. The gonorrheal discharge usually disappeared in eight to twenty-four hours.

In a total of 96 cases there were failures in 11—a recovery rate of 89 per cent—with the use of at least 300,000 units (50,000 units every three or four hours) in over three-fourths of the patients treated. The results are comparable to those obtained when approximately 100,000 to 150,000 units of penicillin is injected intramuscularly. The fact that 10 failures occurred in female patients is in keeping with the premise that the criteria as well as the achievement of cures of gonorrhea may be somewhat more difficult in females than in males when oral penicillin is employed. Regarding the optimal dose of oral penicillin in the treatment of gonorrhea, no categorical statement is possible until a greater number of cases have been treated.

It is important to emphasize the fact that the indiscriminate use of oral penicillin in the treatment of gonorrhea without adequate supervision should be discouraged. All patients should be serologically tested for syphilis prior to the institution of therapy, and the tests should be repeated at monthly intervals for three months to avoid the possibility of giving subcurative doses to those with associated syphilis.

Subacute Bacterial Endocarditis

It was deemed of some academic interest to attempt to treat a case of subacute bacterial endo-

carditis with penicillin administered orally when the organism was relatively sensitive. The case summary is as follows:

Physical examination revealed a well developed and well nourished girl who appeared pale but not acutely ill. No petechiae were noted. The second left upper molar tooth was decayed and loose. A harsh loud systolic murmur with maximum intensity in the 3rd and 4th interspaces about 2 cm to the left of the sternum was present and was transmitted over the entire precordium. There was an intense systolic thrill in the area where the murmur was loudest. The spleen was not palpable, and the remainder of the physical examination was negative. The temperature was 103°F, the pulse 128, and the respirations 27. An electrocardiogram was normal. A roentgenogram of the chest showed moderate enlargement of the right and left ventricles.

Three cultures taken on April 21, 22 and 24, respectively, showed the presence of thirty, forty-four and twelve colonies of *Streptococcus viridans* per cubic centimeter of blood. The strain showed a sensitivity range to penicillin of from 0.05 to 0.1 Florey units. Repeated sedimentation rates ranged between 30 and 45 mm per hour (Wintrobe), and a hemogram showed evidence of a moderate degree of anemia.

The temperature during the first 2 weeks under observation showed a daily rise between 100 and 103.4°F. Specific therapy was started on April 29. Sodium penicillin was prepared in double gelatin capsules, and 100,000 units was given every 3 hours. The patient was given a soft, fat-free diet with moderate limitation of fluids, and the feeding schedule was slightly changed so that at no time was penicillin given simultaneously with a meal. Eight hours after the initiation of oral penicillin the temperature fell from 102°F to normal and remained normal thereafter except for a transient rise to 100°F on the 9th day, at the time of the extraction of the decayed tooth.

A blood culture obtained 12 hours after the start of treatment showed no growth, and daily blood cultures taken during the entire period of 2 weeks during which the patient received penicillin were negative. Penicillinase was added to the broth in one of the cultures, and no growth was observed.

The patient received 100,000 units of penicillin as a single dose every 3 hours for 14 days—a total dose of 11,300,000

case. No toxic symptoms were observed. White-cell counts made every other day were normal, the sedimentation rate, however, remained moderately rapid. Five blood transfusions of 2.0 cc. were given over a period of 2 weeks to combat the anemia.

The patient was observed in the hospital for an additional 9 days after penicillin had been discontinued, blood cultures during that period were negative. She was discharged on May 21 and was examined every 2 weeks for the ensuing 19 months. The child was given complete freedom in her range of activity except for the avoidance of exhaustive play. The daily temperature reading was recorded. She remained afebrile, numerous blood counts were normal and blood cultures taken at frequent intervals during the follow-up period remained consistently sterile. She gained 15 pounds in weight. A roentgenogram showed no change in the cardiac dimensions.

Another patient with subacute bacterial endocarditis due to *Str. viridans* superimposed on a congenital cardiac defect was similarly treated for a month, during which 20,000,000 units was administered. Blood cultures, however, remained positive intermittently during that interval, and after what was considered a fair trial, the oral method of administration was abandoned and the intramuscular route was initiated.

In spite of the striking results obtained with the oral administration of penicillin in one of these cases, subacute bacterial endocarditis is of such gravity that the use of the oral route in this disease is not recommended. Undoubtedly, cures could be obtained in some cases, but parenteral administration offers a more reliable mode of therapy and is the treatment of choice.

Pneumonia

A series of 17 cases of pneumonia were treated with oral penicillin. Of these, 12 occurred in children varying in age from three to twelve years, whereas the remainder were in adults. A pneumococcus was isolated in 9 cases in the pediatric age group, and a hemolytic streptococcus was the causative organism in the other 3. The 5 cases in adults were due to pneumococcus, and in 2 of these positive blood cultures were obtained. Penicillin sensitivity determinations were not done. In all cases the patients were mildly to moderately ill prior to the initiation of therapy.

The usual dosage was approximately 50,000 units every three hours in 15 cases and 100,000 units every three hours in the other 2 cases. Penicillin therapy was maintained usually for forty-eight to twenty-two hours after the temperature had returned to normal. The total oral dose varied between 500,000 and 2,000,000 units in 16 cases, and in the other case 8,000,000 units was used, the average dose in the 17 cases was 1,500,000 units.

With the exception of one patient, the duration of therapy varied between one and a half and seven days, with an average of four and a half days per patient. The temperature returned to normal by crisis usually within twelve to thirty-six hours after the initiation of therapy in 14 cases, and prompt clinical improvement was observed. In no

case was a recurrence of fever or leukocytosis, or both, following termination of therapy noted. There was no perceptible difference between the response of the adults and that of the children in this series.

In 3 cases the temperature came down by lysis during a period ranging from three to eight days, and slow resolution of the pneumonic process was observed, requiring six to twelve days. In 1 patient, an acutely ill eleven-year-old boy, pneumonia due to a Type 14 pneumococcus was complicated by an empyema at the time of admission. He received 480,000 units of penicillin orally each day, a total of 8,000,000 units being given for the eighteen-day interval during which therapy was maintained. In addition, 40,000 units of penicillin was injected into the pleural cavity on three alternate days. Recovery was gradual, the temperature slowly returning to normal by lysis over the course of eight days and the empyema subsiding.

The results obtained with penicillin administered orally in the treatment of pneumonia both in adults and in children indicate that, in the majority of cases, such therapy is efficacious if the drug given is in sufficiently large doses. The total dose used was approximately three to four times the parenteral dosage usually employed. The recommended dose must be predicated on the severity of the pneumonia at the time of admission, a schedule of 50,000 to 75,000 units every three hours for a total of 1,500,000 to 2,000,000 units, however, seemed to be adequate in the majority of cases, although it should be pointed out that two thirds of the patients were children. Pneumonia complicated by empyema is probably best treated by parenteral rather than oral administration of penicillin, together with intrapleural instillation of the drug.

Syphilis

Penicillin was administered orally in 3 adult cases of early syphilis. The dosage schedule consisted of 50,000 units of calcium penicillin in tablet form every four hours for twelve days, or a total of 3,600,000 units.

In 1 case the quantitative Kahn titer was 20 units prior to the initiation of therapy, and the serologic tests became negative within three months, a relapse occurred two and a half months later, however, and the serologic test was still positive after a seven months' follow-up period.

In the other cases, the quantitative serologic estimations were 120 and 260 Kahn units respectively prior to treatment, and in both cases the tests were negative after a six to eight months' follow-up period. One of these patients experienced a mild Herxheimer reaction.

In 10 other patients with syphilis, the lesions that had been dark-field positive became dark-field negative within eighteen hours after the administration of 100,000 units of penicillin by mouth. Herx-

heimer reactions were noted in 3 cases. No attempt was made to treat the patients fully with penicillin by mouth, since the object of this preliminary trial was to determine the rapidity and the dose required to produce dark-field negativity.

In the 3 cases fully treated penicillin given orally produced serologic reversals with a total dose of 3,600,000 units. In 1 case, however, a relapse occurred within five and a half months, and the follow-up examination in the other 2 cases was too short to permit any statement regarding the permanency of the negative serologic tests obtained. It is possible that a total dose of 5,000,000 to 10,000,000 units is required in early syphilis if penicillin is administered orally.

In view of the several complexities in the management of a case of syphilis with penicillin and the relatively high percentage of relapses, the demonstration of serologic reversals with the oral administration of penicillin is probably of academic interest only, at least for the present, except in cases in which the patient is treated in a hospital and observed closely, with serial quantitative serologic examinations following termination of therapy. Unless it is rigidly controlled, such therapy introduces the additional hazard of attempts at self-medication and the administration of subcurative doses.

Miscellaneous Infections

Twenty-three cases of cellulitis in children ranging in age from three to eight years were treated with oral penicillin. The cellulitis involved various sites, some cases having associated abscess formation. A three-hour divided dosage schedule ranging from 25,000 to 50,000 units was employed, with the total dose varying from 240,000 to 1,110,000 units. Hot moist compresses were used concomitantly, and when fluctuation occurred, the area was incised and drained. The organism in the majority of cases in which pus was obtained was either hemolytic staphylococcus or streptococcus. The results paralleled those obtained with parenteral administration of penicillin when the drug was given in approximately one third to one fourth the oral dose.

Five cases of impetigo in infants ranging from two months to two years of age showed a prompt response within two to four days after the oral administration of penicillin varying in dosage from 400,000 to 900,000 units.

Four cases of acute pharyngotonsillitis due to a hemolytic streptococcus responded well to 800,000 units of penicillin administered orally on a dosage schedule of 50,000 units every three hours.

SUMMARY

Penicillin was administered orally in a total of 150 cases, including gonorrhea, subacute bacterial endocarditis, pneumonia, syphilis, cellulitis, impetigo and acute pharyngotonsillitis.

The commercial penicillin tablets used in this study were effective in penicillin-susceptible infections if given in sufficiently large doses.

The fundamental principles of penicillin therapy when the oral route is employed do not differ materially from those attendant on the parenteral administration except for the greater oral dose required.

In view of the relatively small number of cases as well as the age range, in this series, no categorical statement is possible regarding the optimal oral dose of penicillin. The dosage varies from case to case, depending on the severity and type of infection. The inadvisability of indiscriminate oral administration is emphasized.

THE TREATMENT OF HYSTERIC AMNESIA BY PURELY PHARMACOLOGIC MEANS

ABRAHAM MYERSON, M.D.*

BOSTON

PERHAPS no condition is fundamentally so psychologic and without any obvious organic background as hysteric, or functional, amnesia. This condition usually arises abruptly and may disappear as suddenly. It is difficult to conceive of an organic or physiologic basis for a memory loss in which the whole or a large part of the past, often including personal identity, so far as the consciousness of the patient is concerned, is lost for long periods and without the slightest evidence of any neurologic disturbance.

Several kinds of treatment have been instituted for this condition. One is, simply, by the stimulation of the association processes and by psychologic mechanics, to reopen the shut-off field of memory. The second and popular means utilizes hypnosis, the effort being made to delve into the unconscious, to reach motivations for the "escape" process and, by suggestion during and after hypnosis, to cure the amnesia. Still another method is that of psychoanalysis, which in general follows the main directions of this elaborate process, seeking to release the tensions and obstructing mechanisms and thus to integrate the split personality. More recently pharmacologic methods have been developed that have been used mainly in military service and date back earlier than Lindemann's¹ initiatory work on amylal sodium. By the production of narcosis and either by analysis²⁻⁴ or synthesis⁵⁻⁷—these terms indicate the attitude of the worker rather than any really new development—the technic seeks to reintegrate the patient. The workers with these methods have stressed the psychologic factors, since the emphasis has been laid on the assumed fact that the narcosis, or drug effect, merely gives a handle by which psychotherapy can be applied.

In the treatment of 3 recent cases of hysteric amnesia in private practice, an effort was made to exclude psychologic methods and narcosis and to use drugs that have profound central effects. In certain researches on the effect of amphetamine (Benzedrine) sulfate and similar drugs on amylal sodium narcosis, it was noted that when the two drugs were given simultaneously, narcosis was not reached, a mood was produced that can be called exhilaration, or something akin to it, and perhaps more pertinently, a garrulity was noted, often of great intensity in a good many of the patients. Therefore, I utilized the combined effect of amphetamine sulfate—or of Pervitin Hydrochloride

(d-N-methyl amphetamine hydrochloride), which is a similar drug and which on the basis of the literature and personal experience appears to have a greater central effect than amphetamine, as well as producing a greater tendency toward loquacity—and amylal sodium given by mouth in such combined dosage that nothing that could be called narcosis resulted, since only 1 patient became even sleepy. The reorganization of the memory, which was spontaneous and immediate in 2 cases, was brought about in 1 case by simple questions such as those indicated in the case reports presented below. In all cases an effort was made to exclude any analysis of the psychologic situation of the patient both prior to and after the amnesia. Only enough history was taken to establish a diagnosis, and treatment was instituted immediately. No explanation was made, and the therapist excluded his personal influence so far as possible. The results clearly show that pharmacologic methods alone are sufficient to restore the memory of a patient suffering from a profound hysteric or functional amnesia, and that the successful treatment, so far as the immediate problem of restoring the lost memory is concerned, is of the simplest possible order. The treatment of these cases demonstrates a fact that does not seem to require emphasis—namely, that psychologic states are as clearly accessible to pharmacologic treatment as to any other form of treatment.

Two of the cases were post-traumatic, Case 1 arose without any such etiology. In all cases, speculation might easily reveal deep and dynamic psychologic causes.

CASE 1 A 45-year-old Jewish man found the nature of his work in a defense plant intolerable or, at any rate, disagreeable. He complained a good deal and said that there was much anti-Semitism and that other workers played tricks on him. He grew increasingly irritable, developed insomnia and other neurotic symptoms, and one day became quite violent, excited and noisy while at work. He was taken to a hospital for a short time, after which his family took him home. He had a complete amnesia, which stubbornly persisted after his excitement had entirely disappeared. The amnesia was not only for the period of his work at the defense plant, but for practically everything in the previous 10 years. He could remember his childhood. He did not remember his marriage, nor did he acknowledge his wife stating that he did not know her. This attitude was maintained unswervingly for about a month, when I saw him for the first time.

The patient was in excellent physical condition, presenting no signs of organic brain disease—in fact, it is clear that such an amnesia is not possible as a direct result of an organic brain accident or injury. From the time of the onset of his illness to the time when I first saw him, his recent memory was intact—that is, the recent experiences were perfectly well assembled, organized and recalled, although

*Professor emeritus of neurology Tufts College Medical School formerly clinical professor of psychiatry Harvard Medical School director of research Boston State Hospital

past memories and associations for at least 10 years were entirely absent from his consciousness.

Without in any way indicating the purpose of the treatment, I placed the patient and his wife in a separate room in my office suite. He was then given 0.2 gm (3 gr) of amytal sodium and 15 mg of amphetamine sulfate by mouth. I left the room and returned in 45 minutes. I then asked the patient if he recognized the woman to whom he was talking. He immediately answered with a long and detailed statement, speaking rapidly and with some degree of incoherence, that certainly he recognized her. She was his wife, he went on to answer questions about his past life, sometimes with a slight hesitation, and at other times with none whatsoever. He talked about 1 hour, almost constantly, and at the end of the time had practically reassembled his whole past.

This patient was last seen in June, 1942, and has remained well since then, there has been no gap whatever in his memory.

CASE 2 In this case, the amnesia was much more complete, since the patient completely forgot everything in the past history, including his own identity. This patient, a 50-year-old foreman in a factory, was a skilled mechanic whose past history was entirely free from any overt psychopathology. He was regarded as a well organized, industrious, self-disciplined and controlled person who had nothing resembling a neurosis of any kind. About a year before the time he was first seen, one of his sons had given him a great deal of trouble, which hurt his decided pride in his family name. Although he seemed concerned and humiliated, he continued to work steadily and satisfactorily, carrying out his responsibilities as well as ever. Then while at work he received a blow on the head that was not severe enough to create unconsciousness but was of sufficient momentum to daze him. The back was wrenched at the same time. He complained of severe headache but returned to work the next day, seemed forgetful and confused and complained of the pain in the back and the head almost constantly.

Within 48 hours he became "very wild," ran out of his place of work, assaulted a policeman and talked wildly about the people who were trying to destroy him and his family. He was overpowered, given sedation and quieted down quickly. He was taken home and from that time on until he came to see me 6 weeks later, he presented a complete amnesia. He remembered nothing of his past. He accepted his name as being his own, but he did not remember it. He did not recognize his wife, two devoted sisters or his children. He knew nothing whatever of the place in which he had worked, nor was he able to give any information about his past, his education, his training, his work or any of his experiences. When he came to the office, he stated, "This woman says she is my wife, and this woman states that she is my sister." He was not in any way friendly toward them. He was not affectionate, in fact, he rather resented their solicitude. His answer to every question concerning his past was "I don't remember. I am told I am so and so, but from my own knowledge I do not know who I am." It was stated, and he agreed, that some things in the town in which he lived seemed familiar to him, and he had on one occasion used the name "Bill" to denote a man whose name was Bill, but he could not give any information concerning this man. He said that this memory had "popped" into his head. It was clear that this amnesia was functional and that no organic lesion could wipe out a man's entire past and leave him entirely coherent and relevant in his speech and without any defect in his recent memories.

The procedure followed in Case 1 was repeated, except that instead of amphetamine sulfate, 10 mg of Pervitin was used, in combination with 0.2 gm of amytal sodium by mouth. The patient was left in the room with a sister and his wife, and I passed on to the care of other patients, until 45 minutes had elapsed. When I returned, the patient, after a short period of slight drowsiness, was talking freely to his wife and sister and recalling spontaneously, to their delight, his past experiences. He passed from one theme to another with great rapidity, remembering things that they had forgotten. He was entirely at ease with them and not only knew them but felt that they were his kinfolk. When I addressed him, he asked them who I was and how he happened to be in the examining room. Within a minute or two, however, he had recalled the circumstances of his coming to a doctor's office, and all the gaps of his memory were soon in a fair way to be filled in. When he reported the next

day, the amnesia had entirely disappeared, and so far as his family could determine, he was entirely normal. He talked of his son's delinquency with some sorrow, but with no undue emotion. No attempt was made to explain the situation to him, largely because I am of the opinion that no adequate explanation can be given, and moreover, because in these cases the attempt was made to cure hysterical amnesia with no psychotherapy.

This man was last seen in May, 1944, and has remained entirely well since then. If there is anything psychopathologic left to be cured by any other means, neither the patient nor his family are aware of it.

CASE 3 A 14-year-old girl, in her 1st year of high school, was recently seen. She had had no emotional difficulties any kind so far as was then known. The family, although poor, lived in harmonious and adequate circumstances. The parents were as kind and understanding as most parents. Her school work was average in its marks and presented no apparent special difficulties. She had plenty of friends. She partook of social affairs freely and joyously. She was too young to have any steady boy friend, but she liked boys and was attractive to them.

Three weeks before I saw her, she went to school in the usual way. It was the morning of a great snow storm. She did not reach the school, and the day went by without an word from her. The parents became alarmed and called the police, and the patient was finally picked up wandering in a distant part of the city. She did not know her name and had no memory of her past. She did not recognize her parents although she accepted the statement that they were her mother and father. She could give no account of what had happened to her. She recognized the fact that other children in the household were her brothers and sisters and the people who came in were her friends, but the sense of familiarity—that is, a chain of memories with a feeling of familiarity—was absent. She seemed apathetic and dull, did not show her usual animation, and was naively bewildered. She remained, practically speaking, in this condition until she was brought to see me. A careful physical examination revealed no evidence of any organic disorder, and again it must be stated that it is not probable that any organic disorder could have produced such a complete amnesia with unimpaired consciousness for the present and its events.

The same procedure was followed as in Cases 1 and 2, except that on the first occasion 0.2 gm of amytal sodium and 10 mg of amphetamine sulfate were used with relatively little effect, the patient could recall the school she had attended recently, but questions had to be asked for every fact obtained—for example, when asked whether she remembered her teacher's name, after a long pause she assented and gave the name. There was little spontaneous recall, and although some progress was made by the question-and-answer method, the results were not satisfactory.

The patient reported the next day, when 0.2 gm of amytal sodium and 10 mg of Pervitin were administered. In about an hour she was questioned about her past. She answered quickly, easily and interestedly. Spontaneously she went on from one fact to another and gave details about the people she had known, often with a humorous twist. She proceeded from the subject brought up to a related subject, bridging the gap with a statement such as "Oh, yes, and now I remember." By the end of this interview she was gay and, moreover, expressed her gratitude to the physician for his help. She recognized that she had lost her memory and went on suddenly to tell how the amnesia had happened—in other words, to fill in the events of the day on which her memories had become displaced. On her way to school that morning, as she reached a place near it, several boys had thrown snowballs at her. In her frightened attempt to dodge the missiles, she had slipped and fallen heavily on the ice, striking her head. She had got up dazed and from that time had wandered around in the amnesic state. After her recovery, however, she was able to give details of the places that she had visited, and as she related the happenings of the morning, her face became quite animated and excited while she went from event to event.

This child required one more treatment before all the gaps in memory were filled in, and she completely re-integrated her past and present life and re-formed the bonds of recognition and easy familiarity with the people and things of her milieu. She then came in to see me with a statement

of the conditions of her school attendance, which gave at last a plausible explanation of her break up into hysteric amnesia on the occasion of the snow-ball throwing. There were four "tough" girls in her class who took a delight in malicious teasing and assaulting her. They mocked and defied her genteel manner. They tripped her as she went by them, and on one or two occasions, they roughly handled her, so that going to school each morning was an ordeal and there took place a greater and greater reluctance to enter the school portals. She reached school each day in a state of acute terror, and this terror persisted throughout the whole person. Thus, the main conscious feature of her school attendance was the fear of what these girls might do next. It is conceivable that on the basis of this fear, the assault by the boys with snowballs and her consequent fall brought about the dissociation of hysteria. The fall was merely the immediate physical and psychic trauma to a personality already disorganized by chronic anxiety. This is true of the other cases and probably also of the amnesias that take place in war.

This patient was last seen in March, 1945, and has recovered well since then.

It is not contended that all cases of hysteric amnesia are treatable by this simple means. Certain ones are far more complicated in psychologic mechanisms and social entanglements than the cases cited above. For example, a young woman whose mother was psychotic and had received shock treatment and whose husband had been discharged from the Army with a diagnosis of psychoneurosis lived in a domestic atmosphere of turmoil and unhappiness that might have been expected from the fact that she and her husband lived with the mother. There were constant bickering, quarreling and extreme emotional tension in the household. From time to time she had unconscious attacks, which were really hysteric attacks and following which there was an amnesia for a considerable period of the time prior to the attack. Each attack was easily cleared up by the use of these drugs, but the treatment in no way prevented further attacks from taking place. During the amnesia, there was stuttering, which was also helped by the drugs but which tended to recur during another attack of amnesia. In this case treatment had to be much more drastic than the simple administration of the drugs, with a change in the whole setup between the patient and her husband and her mother before any lasting therapeutic result was obtained. It should be added that a good deal of so-called "hysteric amnesia" is malingered, and one must be on one's guard at all times in judging whether or not an amnesia is hysteric or faked.

The essential feature of the treatment of the cases presented above seems to have been in the breaking down of abnormal inhibition and personality attitude that takes place under the influence of powerful drugs and, perhaps more importantly, the drive given by these drugs to communication, the uncon-

scious reticence that is probably the basis of the amnesia being dissolved. To speculate quite without proof, something is set up that says, in essence, "I do not want to remember, I cannot remember." The impetus of the drugs removes this negativism and thus brings about cure. In catatonic dementia praecox, as shown first by Lindemann¹ with amytal sodium narcosis, the same result is obtained temporarily, in that the patient who has been noncommunicative talks freely after the drug narcosis, but, as the effect of the drug wears off, the catatonia reasserts itself. Since hysteric amnesia is a relatively mild disorder, the effect of the drugs seems to be lasting.

The pharmacologic effect of the two drugs used, as pointed out in previous publications,^{8,9} is reciprocal. As Lindemann's work showed, amytal sodium breaks down negativism and the mutism that goes with it, whereas amphetamine sulfate and, especially, Pervitin not only prevent the narcosis but also have a definite pushing effect, synergistically with the sodium amytal, on the verbal association processes. The combination seems to be ideal wherever one desires to increase communication and especially in the great field of the psychologically hidden.

SUMMARY

Three cases of undoubted hysteric amnesia occurring rather suddenly in relatively normal people are presented. The effort was made to exclude psychotherapy and also the use of narcosis. To accomplish these ends, a combination of amphetamine (Benzedrine) sulfate or an equivalent drug and amytal sodium was administered in such doses as not to produce narcosis. Increased communication took place, and there was immediate or relatively immediate dispersal of the amnesia.

METASTATIC MELANOCARCINOMA INVOLVING THE SMALL INTESTINE AND BRAIN*

Report of a Case, with a Discussion of Malignant Tumors of the Small Intestine

JACK SPIER, M.D.,† AND EDWIN C. WOOD‡

WASHINGTON, D. C.

REVIEWING the recent literature concerning diseases of the small bowel, one is impressed with the infrequency of reports of malignant tumors. Narrowing the field of interest to melanomas occurring in the small bowel certainly increases the task of locating appropriate material in many cases. With these points in view this paper is directed toward a broad comparative survey of the occurrence of malignant lesions in the small intestine, with special emphasis on melanomas.

In about 10 per cent of cases at autopsy a carcinoma is found somewhere in the body. A review of 137,174 cases gathered from various hospitals by Shallow, Eger and Carty¹ revealed primary malignant tumors of the large intestine in 3.66 per cent, the small intestines being named the origin of malignant growths in only 0.098 per cent. Both carcinoma and sarcoma may develop in the small intestine. Shallow et al.¹ also state that 3 per cent of intestinal carcinomas and 60 per cent of intestinal sarcomas occur in the small bowel. Carcinoma is twice as frequent as sarcoma in this location, despite the percentages cited above, since sarcoma of the intestines is such a rare finding. The importance of this distribution and its effect on the signs and symptoms produced and on the success of diagnosis are referred to below.

Adenocarcinomas compose about 90 per cent of the small-bowel carcinomas and in most cases are of the napkin-ring type, but they may be polypoid and ulcerative.² To step into more controversial territory it may be mentioned that many authors have reported cases of malignant carcinoids in the small intestine and have attested their malignancy by giving evidence of widespread metastases.³⁻⁵ Most authors agree that there is a rather pronounced tendency for the carcinoid to be malignant when it is located in the gastrointestinal tract in sites other than the appendix, although the appendiceal lesion behaves like any benign tumor.

A melanoma in the small intestine is a rare tumor, whether it is regarded as primary in the bowel or as a metastasis from some other site. Herbut and Manges⁷ in a survey of the literature cited only 25 cases, of which 9 were reported as primary in the small intestine and 16 as metastatic lesions. Ewing⁸ states that melanoma of the intestine occurs

almost exclusively in the rectum. The rarity of the lesion can easily be shown by the fact that the general texts of pathology make no mention of such a lesion of the small bowel.

It is interesting to note that several authors have made attempts to explain the relative infrequency of small-bowel as compared with large-bowel tumors. Fraser⁹ suggests that the alkalinity of the intestines, the fluidity of the contents, the lack of sharp bends and the absence of prolonged stasis may explain in part the low incidence of neoplasms in the small bowel. Rankin and Mayo¹⁰ presented the hypothesis that the tumors arise from embryonal rests or develop as a result of some pathologic changes in Brunner's glands. As in all other conditions in which the etiologic agents are still obscure the possibility that some hormonal influence is present must be considered. Perhaps the contents of the bile, the pancreatic juice or the succus entericus plays some part in protecting the small bowel by furnishing an environment adverse to tumor growth.

There is considerable disagreement among the various writers about which areas of the small intestine are involved most frequently. According to Swan,^{11, 12} carcinoma involves the duodenum and ileum with equal frequency and attacks the jejunum less often. Shallow's¹ survey of a large number of cases is somewhat at variance with this statement—he has found that the malignant process involves the three parts of the small intestine with equal incidence and that the ileum ranks lowest for carcinomas but highest for sarcomas. Within the duodenum, carcinoma is most frequent in the second part, less frequent in the first part and quite rare in the third part.¹³ The carcinomas found in the first part of the duodenum are usually lesions that have developed as a result of the extension of carcinoma of the head of the pancreas or, more rarely, carcinoma of the pyloric end of the stomach into the duodenum via the subserosal lymphatic vessels or by implantation of the serosa.¹⁴ The high incidence of tumors occurring in the second segment is explained in part by the entrance of the common bile duct into the duodenum. It is a known fact that the junction of two different types of epithelium predisposes to the development of cancer,¹⁵ as attested by the frequency of carcinoma of the lip or rectum developing at the mucocutaneous junction. It is usually stated that the sarcomas are oftenest found in the terminal ileum and jejunum. One cannot make a definite statement regarding the

frequency of melanomas in the various areas of the small intestine, since the vast majority of the melanomas have been reported as secondary lesions metastatic from some other focus. Thus, chance alone determines whether the tumor emboli lodge in the blood and lymphatic vessels supplying the duodenum, the jejunum or the ileum. Few authors have been so bold as to claim discovery of a melanotic tumor primary in the small intestine.

The order of metastasis of primary intestinal cancers to other organs seems to be as follows: the mesenteric lymph nodes and peritoneum, the liver, the lungs, the long bones, the dura mater and the spinal cord.¹⁸

The patients who suffer from carcinoma of the small bowel are usually within the classic cancer-age group. Figures by Fraser⁹ give the average age as between fifty-two and fifty-six years. Ullman and Abeshouse claim that thirty-three years is the average age for sarcoma of the small bowel. Men and women seem to be affected by the malignant tumors with equal frequency, although the lesions seem to develop at an earlier age in women than in men.

CASE REPORT

M. C., a 55-year-old woman, was admitted to the hospital on February 14, 1946, because of faintness, nausea and vomiting on two occasions during the previous 2 months. In December, 1945, the patient had fainted after smelling cigarette smoke. She was unconscious for a few minutes and on awakening vomited three times. She was taken to a hospital, where she remained only a few hours. About a week prior to this episode, the patient had also fainted after smelling cigarette smoke, had been nauseated and had vomited. She felt weak and dizzy. She had had no convulsions at any time but had noticed incontinence. She suffered from frequent dizziness accompanied by dimness of vision and also had generalized severe headaches. She had a poor appetite and could take only liquids.

Neurologic examination revealed the cranial nerves to be intact. All tendon reflexes were hypoactive, and the Babinski reflex was negative. The abdominal reflexes were not elicited. There was difficulty in distinguishing between sharp and dull sensations in both lower extremities. The patient could not distinguish the position of toes. Romberg's sign was positive, indicating impaired strength in the left lower extremity. The pupils reacted to light and accommodation. There was no strabismus. All other findings were essentially negative, except that the patient had no regular bowel movements and had to take laxatives at least once a week. She stated that five years previously a carcinoma of the shin bone of the left leg had been surgically removed. In the hospital a neuro-ophthalmogram was done. The patient did not rally afterward and gradually failed; she died on February 21.

Autopsy. Post-mortem examination showed the body of a well-developed, well-nourished woman who appeared to be of stated age. There was a well-healed, 5-cm-long scar on the medial aspect of the left leg. On section there was no free fluid in the abdominal cavity. The liver edge extended two fingerbreadths below the right costal margin. There was no free fluid nor evidence of adhesions in either pleural cavity. Examination of the heart disclosed no gross pathological findings throughout the chambers, valves and appendages. Both coronary ostia were patent. The aorta showed a moderate amount of atheromatosis. The left lung was slate blue, with the usual anthracotic pattern. The cut surfaces were feathery and dry. The right lung showed a similar picture. The hilar lymph nodes were normal in size and consistence. The liver was smooth and reddish brown. It was of normal consistence, and section disclosed mild congestion. The gall bladder revealed nothing of importance.

The spleen was grayish blue, and on section the pulp was fleshy and congested. Section of the pancreas and adrenal glands showed their respective normal architecture. The kidneys, which were slightly smaller than usual, were purplish red. The capsule stripped with little difficulty and revealed a beginning fine cortical granularity. On section the corticomedullary ratio was preserved. The ovaries were small, grayish white and dense. The left ovary presented a cyst measuring 1.5 cm in diameter. The uterus was somewhat atrophic. The esophagus and stomach showed no gross abnormalities. In the first part of the ileum, three ulcers across

FIGURE 1 Photograph of the 'Ulcers' in the Ileum

the circumference of the bowel were visible. Each ulcer was separated from the other by about 5 cm of normal mucosa. The lesions showed raised, rounded edges and were shallow (Fig. 1). The floors of the ulcers were covered with a slight greenish-gray exudate. Each ulcer measured about 2.5 cm in diameter. The surrounding mucosa was not infiltrated. The indurated edge of each ulcer was well delimited. One centimeter distal to the last large ulcer, a smaller ulceration, 0.5 cm in diameter and similar to the others in all respects but size, was noted. On the serosal surface over each ulcer there were a few yellowish nodules of pinhead to split-pea size that appeared to correspond with the edges of the ulcerations. There was no penetration or thickening of the serosa over the craters of the ulcers. Otherwise, the remaining small bowel and large intestine were not remarkable. The lymph nodes showed no involvement on gross examination. The lesions were grossly diagnosed as multiple ulcers of the first part of the ileum of undetermined etiology.

The histopathological diagnoses were bronchial dilatation, emphysema, atelectasis and bronchitis of the lungs, central congestion and beginning fatty metamorphosis of the liver, congestion, reticulum fibrosis and capillary sclerosis of the spleen, congestion of the adrenal glands, periductal fibrosis and slight lipomatosis of the pancreas, congestion of the kidneys, with beginning arteriosclerosis, follicular cyst left ovary, and partially necrotic tumor tissue of the ileum. The tumors presented a somewhat alveolar pattern (Fig. 2). In some areas the arrangement could be called pseudopapillary. The cells were large and polyhedral. A few small anaplastic cells were seen. The nuclei were hyperchromatic, and a moderate number of mitoses were apparent. A small amount of brownish-yellow pigment was seen in some fields, being contained within a somewhat more fusiform type of cell. The tumors contained a few small non-invaded blood vessels. The lymph spaces in the serosa of the intestine showed clumps of tumor cells. The diagnosis was melanocarcinoma.

Sections through the midbrain and cerebellum revealed hemorrhagic areas in the raphe of the peduncles and in the superior portion of the right cerebellar hemisphere. Section through the corona radiata showed a spongy lesion (3 by

4 cm) with somewhat ragged but well defined borders (Fig 3). The lesion was dark brown. Similar lesions were observed in the left frontal operculum and in the right temporo-occipital region, and others were encountered in the right temporal lobe at the level of the anterior commissure, in the occipital lobes and in both frontal lobes. The histologic picture of the tumor masses was identical with that of the tumors found in the small bowel, but a more pseudo-peritheliomatous pattern was present*.

In this case there were no abdominal symptoms or signs that could be attributed directly to the intestinal lesions. There was a history of a "carci-

noma" removed at an earlier date. Four ulcers in the ileum were diagnosed microscopically as melanocarcinomas. There were multiple melanocarcinomas involving the brain. It is unfortunate that complete information concerning the tumor removed at an earlier date could not be obtained, since classification of the tumor would probably have aided in the solution of some of the problems presented.

FIGURE 2 Photomicrograph of a Section of One of the Tumors of the Ileum ($\times 80$)

noma" removed at an earlier date. Four ulcers in the ileum were diagnosed microscopically as melanocarcinomas. There were multiple melanocarcinomas involving the brain. It is unfortunate that complete information concerning the tumor removed at an earlier date could not be obtained, since classification of the tumor would probably have aided in the solution of some of the problems presented.

DISCUSSION

A primary consideration in melanoma is its relation to the pigmented nevus. Benign pigmented nevi, or pigmented moles, are seen on the skin of almost every man, woman and child. The average person is born with approximately fifteen to twenty of these spots.¹⁷ They may be light or dark, flat or raised and hairy or smooth, and they may vary

*We are indebted to Dr. Walter Freeman for the information concerning the brain lesions.

FIGURE 3 Photograph of the Brain, Showing the Various Tumors

from a fraction of a millimeter to several centimeters or more in size. They are quite innocent and demonstrate no invasive qualities. They occur particularly on the face, neck and back but are frequently seen in large numbers on the extremities. These benign nevi are usually responsible for no more discomfort than any other slight skin blemish. In some cases, however, innocent nevi undergo malignant changes, generally owing to the constant irritation of repeated rubbing or cutting. Therefore, the nevi that are likeliest to become malignant are in areas of the body exposed to continual chafing and disturbance—for example, on the neck at the collar line, on the heel of the foot or on the face in the path of the razor's edge. A nevus that has undergone malignant change is known as a malignant melanoma or simply a melanoma, a term first used in 1836 by Carswell. Approximately 32 per cent of the melanomas arise from nevi.¹⁸ Studies on the early changes of nevi into melanomas show that the important signs and symptoms of a potential malignant process consist of a history of trauma, itching, growth of the nevus, pain and inflammation.¹⁹ The melanomas of the skin usually do not develop into large tumors despite their high malignancy.

A characteristic trend seems to be the tendency toward a rather long latent period between the operative removal of the melanoma of the skin and any evidence of visceral metastases. According to DeCholnoky¹⁵ metastatic lesions occur within six months to two years of the recognition of the skin lesion. Many exceptions occur, however, and metastasis from a melanoma of the skin has been reported as late as ten to twenty years after removal of the primary tumor. This latent period is shown clearly by the case presented above, in which signs of metastasis were delayed for five years.

Metastasis usually begins by an infiltration into the surrounding skin area, and the first metastatic lesions are usually in the skin. Next, the regional lymph nodes are involved. The tumor cells multiply within the lymph nodes, replacing the normal architecture, and eventually invade the capillaries within the node. Further extension then occurs rapidly via the blood stream.¹⁸ Although this is the usual method of spread, an early, direct blood-stream invasion may occur. Ewing⁸ thought that the method of early spread is usually by the lymphatic vessels. He further claimed that hematogenous spread is late and generally extensive, missing hardly an organ. It is interesting to note that in the case presented above only two organs were involved, if the lesions in the ileum and brain are regarded as metastatic. Obviously, any form of lymphatic spread can be excluded, since there were no obvious lymphatic connections between the areas of tumor involvement. The only possible method of metastasis in this case seems to have been that of hematogenous dissemination. Contrary to Ewing's statement that a large number of organs are affected when tumor spread is via the blood, however, only two organs were involved. No logical explanation can be advanced to explain this discrepancy. No definite sequence of spread to the various organs can be given in cases of hematogenous spread, since the lodging of tumor emboli in the various organs is largely a matter of chance.

Another common site for the development of melanomas is the eye. Ewing states that about a third of all the melanomas have their origin in the choroid layer of the eye. Metastasis may be delayed in this type, just as in the melanoma of the skin. Melanomas also arise from the brain, the adrenal glands and the rectum at the mucocutaneous junction.

Few reports have proposed the presence of primary melanomas in the small bowel. Herbut and Manges,⁷ in a review of the literature on intestinal melanomas, located only 9 such cases. Obviously, the plausibility of such reports depends on a concept of the tissue of origin of the melanoma that is by no means definitely established. There are two chief schools of thought, one group stressing the role of the melanoblast as the chief cell involved in the formation of the tumors and the other,

headed by Masson, championing the cells of the Meissner and Merkel-Ranvier complexes that occur in the skin. Laidlaw²⁰ has made an extensive study of melanoblasts and the dopa reaction on material at autopsy and has concluded that melanoblasts, which he considers responsible for the tumor formation, do not exist in the small intestine. Furthermore, there are no melanoblasts in the colon or in the rectum above the mucocutaneous junction. Therefore, he concludes that the occurrence of primary melanomas above this junction is improbable and that if these tumors do occur they must arise from misplaced islets of ectoderm. We are not aware of any reports that the Meissner and Merkel-Ranvier complexes exist in the intestinal walls, and on this basis, a neurogenic origin of a melanoma in the small intestine can be ruled out. Thus, it appears to be quite risky to diagnose a primary melanoma of the small bowel on the basis of present knowledge. Herbut and Manges⁷ point out that the eyes, which, as previously mentioned, are often the source of melanomas, are usually not examined adequately enough in the routine autopsy to rule out melanoma of the eye. Consequently, they conclude that "without a thorough examination of the eyes a diagnosis of primary melanoma of the small intestine should not be made." It is our belief that on the basis of the evidence presented in the medical literature, one cannot convincingly show how melanotic tumors arise primarily from the small intestines, except as the result of the aberrant displacement of cells during the early periods of body organization.

The clinical course followed in the cases of a melanoma with metastasis to the small bowel is quite interesting. One of the first points that attracts attention is the lapse of time between the removal of a mole and any evidence of metastasis to the intestinal tract. As noted above, the latent period is usually six months to two years. Such an operative history and the typical latent period were noted in the case reported above, but we cannot be sure of the type of tumor removed, although it was probably a melanoma. The signs and symptoms are not characteristic of melanomas alone but should certainly lead one to suspect a malignant process within the gastrointestinal tract. It may or may not be possible clinically to locate the tumor within the small intestine, depending on the size of the tumor, the rapidity of growth, its exact position and its effect on the lumen of the bowel. As in many cases of carcinoma of the gastrointestinal tract, the patient usually presents some history of weight loss and anorexia. Constipation or alternating constipation and diarrhea are frequent complaints. Examination of the blood often discloses a secondary anemia. When the tumor affects the second part of the duodenum, it may produce an intermittent or, later, a continuous jaundice if it involves the ampulla of Vater.

Several complications may add to these general signs and symptoms. In the first place, even though small-bowel tumors are rarely the source of bleeding in the gastrointestinal tract, they must be considered possible causes of recurrent melena.²¹ Bockus¹⁴ states that the bleeding is the most important clinical feature of carcinoma of the small intestine. Since the sarcomas tend to grow peripherally, they may not produce bleeding until late in the course of development. The tumor mass may be responsible for an intussusception, which often gives rise to an acute abdominal episode, and this acute condition is sometimes the first sign caused by the tumor. Frequently, the small-bowel tumor is first noted at the exploratory operation occasioned by such an acute condition. Fiske²² claims that 30 per cent of tumors of the small intestine cause intussusception. A chronic obstruction may be produced by the slow continuous growth of the tumor into the bowel lumen. This is more frequent in carcinoma than in sarcoma, since the former develops in the inner portion of the wall and grows centrally whereas the latter tends to grow toward the periphery. The tumor growth eventually causes perforation of the bowel wall and resulting peritonitis in rare cases.

The actual clinical diagnosis of any tumor of the small bowel is usually quite a difficult procedure and is often made on a basis of a systematic elimination of the possibilities that the lesion is in some other organ. In 38 proved cases reported by Shallow et al.¹ three quarters of the tumors were palpable, being usually fixed in the duodenum but movable in the jejunum and ileum. Sarcomas may be palpated frequently, since they tend to produce irregularity of the serosal surface of the bowel during centrifugal growth. Repeated examination of the stool for occult blood is valuable. Only about 25 per cent of the tumors can be seen on x-ray examination.² Bockus,¹⁴ however, claims that the duodenal carcinomas that are large enough to produce clinical symptoms are usually demonstrable by x-ray study and that in the diagnosis of tumors of the small intestine "progress meal x-ray examination is the only decisive diagnostic method."

The prognosis for patients with carcinoma of the small intestine is quite poor because of the delayed diagnosis and the late surgical removal of the tumor mass. McDougal²³ estimates that 5 per cent of cases reach the stage of five-year cure. Recur-

rences of the tumor in the same region or torrents of metastases may carry these few remaining victims away in later years.

SUMMARY

General statistics and a broad comparative survey of malignant tumors of the small bowel are presented and the infrequency of melanomas in the small intestine is stressed. A case of melanocarcinoma with metastasis to the ileum and brain is presented.

The sites of origin and the methods and order of metastasis are discussed. The possibility of primary melanoma of the small bowel is considered.

The clinical picture of cancer of the small intestine is briefly described.

MEDICAL PROGRESS

GENERAL ANESTHESIA*

CASIMIR HARRIS, M.D.,† AND URBAN H. EVERSOLE, M.D.‡

BOSTON

THE purpose of this paper is to summarize the progress in general anesthesia since the publication of a similar report in 1943.¹ The subject is presented under the following headings: the development of anesthesiology as a specialty, the growing importance of curare, the expanded usefulness of Pentothal Sodium, new technics and physiologic investigations.

DEVELOPMENT OF THE SPECIALTY OF ANESTHESIOLOGY

At this writing, there are approximately three hundred physicians certified by the American Board of Anesthesiology in the United States, and there are over two thousand members of the American Society of Anesthesiologists. Yet the current *News Letter* of the Society lists sixty-three vacant staff positions, as well as one hundred and two residencies or fellowships available in this specialty. The war's end has obviously left the country with an acute shortage of men trained in anesthesiology.

The great shuffling of the medical and surgical population caused by the war may have been partly responsible for a greater interest in anesthesiology. Many surgeons in the armed forces encountered either the best or the worst in anesthesia and, in either event, returned to civilian life appreciating the need for trained anesthesiologists. Mousel et al.² have analyzed the situation statistically as follows:

In the long development of surgery, even the inferior fringes of this specialty have so nearly caught up with the leaders that their gross mortality is only two to three times as great. The fact that in the relatively young specialty of anesthesiology the ratio of worst to best is represented by the ratio of more than 20 illustrates how terribly wide is the gap between what is now being given on our best services and what is being suffered on the worst or even average ones.

The wide variation between the best and average anesthetic practice calls not only for more trained anesthesiologists but also for continued concentrated effort on the part of organized anesthesiologists to raise the standard generally. Establishment of the American Board of Anesthesiology in 1938 was an important step in the progress of anesthesia. This board has done and is doing a splendid job in setting up standards for certification of specialists in anes-

esthesiology and examination of candidates for certification in this specialty.

Evidence of further progress is reflected in the increased demand and the expansion of facilities for postgraduate training in anesthesiology.

Perhaps in no other specialty does the demand for trained physicians so exceed the supply. Furthermore, it is doubtful if any other specialty has been subject to more abuse and exploitation resulting in lower quality of service to the patient. Anesthetists frequently have not been accorded proper recognition, financially or otherwise, for the important part they play in the care of patients. They have resented being relegated to the position of a technician. Yet far too often they have been content to be only technicians and have not been willing to equip themselves to assume the role of a real consultant who not only can carry out a skillful, technical procedure but also, by virtue of a background of fundamental knowledge of physiology, pharmacology and even medicine and surgery, can render a valuable opinion as a consultant.

On the other hand, surgeons have been prone to be content with anesthetic service that is not only short of the best but even short of mediocre. They have failed to realize the value of the proper anesthetic management of patients in the lowering of mortality and morbidity rates. This attitude has frequently resulted in either a conscious or unconscious exploitation of the anesthetist and also of the patient. Furthermore, it has tended to discourage younger physicians from entering this specialty. Improvement in these conditions is evidenced by the fact that there is an increased demand for trained anesthesiologists as well as for training facilities in this specialty.

Waters³ has aptly called attention to the necessity of ridding "ourselves of the generally held belief that the importance of anesthesiology lies in the choice of agents or in the particular technic employed." He calls attention to the fact that through fundamental knowledge and diagnostic skill, quite as much as through artful technical manipulation, the abuses to which all drugs and methods are subject may be either voided or neutralized.

The specialty of anesthesiology may now be practiced by the inadequately trained person neither more ethically nor more responsibly than surgery itself.

THE DEVELOPMENT OF CURARE

Perhaps the most significant drug to be introduced into the field of anesthesia during the past four years is curare

The advantages of curare have been emphasized by many writers⁴⁻⁷ Brody,⁸ describing a technic in which curare is combined with Pentothal and nitrous oxide, observes that upper abdominal operations, "undertaken only with great difficulty and poor relaxation without curare can now be done with excellent relaxation" The total dose of Pentothal is reduced, and the postanesthetic period of depression considerably shortened Potent anesthetic agents may be given in light concentrations, and weak agents may be used for operations requiring maximal relaxation

Although Sir Walter Raleigh described curare to Elizabethan England, only after Gill's⁹ scientific missionary work were investigators presented with a constant supply of raw material that could be standardized Before Gill's experiments culminating in the period 1938 to 1940, there were three main crude preparations emerging from the South American jungles These were tubo-curare, pot-curare and calabash curare, the ingredients depending on the whim of witch doctors or up-river traders As might have been expected of these variable arrow poisons, the century of clinical and laboratory work that preceded Gill led to no accepted therapeutic technics At present, there are two standardized preparations, one more refined than the other Their action is predictable on the basis of a precise bioassay method Intocostin,* the first preparation of curare commercially available, contains 20 mg per cubic centimeter of a highly refined substance, d-Tubocurarine, the second, contains 3 mg per cubic centimeter of crystalline curare and is volumetrically equivalent in strength to Intocostin Tubocurarine is undergoing extensive clinical trial

Curare blocks the response to the nicotinic action of acetylcholine¹⁰ It prevents the effector substance at the myoneural junction of voluntary muscle from responding to the action of acetylcholine The drug also stops the synaptic transmission of impulses between preganglionic and postganglionic fibers of the autonomic nervous system

Clinically, curare causes a progressive selective paralysis and relaxation of the muscles of the head, neck, extremities, abdomen, thorax and diaphragm Good abdominal relaxation is possible without significant depression of respiratory activity Should respiratory paralysis follow an overdose, the effect is transient Complete recovery of function follows a few minutes of intelligent, forced ventilation Most authorities mention prostigmine as the physiologic antidote, but few have had occasion to use it¹⁰

Evidently curare is in part destroyed by the liver and in part eliminated unchanged in the urine

Liver or kidney damage does not, however, prolong or intensify the action Cole⁶ regards impaired renal function as a "relative contraindication"

Cole¹¹ has established that the lethal dose of curare in dogs in the presence of artificial respiration is twenty times the dose producing death by asphyxia from untreated respiratory paralysis Although the mechanism of death in the former instance is not explained, this would be valuable information, for there is no report of any pathologic effects when curare is given to a well oxygenated, anesthetized patient

Comroe and Dripps¹² have reported a histamine-like action of curare in certain patients that produces bronchoconstriction and hypotension Whitacre and Fisher⁵ mention the danger of bronchoconstriction and excessive tenacious salivation in some curarized patients who are too lightly anesthetized, increased depth or more curare will cure these effects Cullen¹⁰ writes that atropine or scopolamine premedication prevents salivation Griffith⁷ found no such need in his series

Loss of consciousness is said to occur with large doses of curare, but the prolonged period of recovery with forced respiration makes surgery under curare alone impracticable⁵ Moreover, the curarized, unanesthetized patient, if conscious, is fully sensitive to pain even when he is unable to respond Curare has no analgesic effect

Many technics for the administration of curare have been proposed^{4-8, 10, 12} The drug has been used with almost all general anesthetic agents After induction the rapid intravenous injection of an average initial dose for an adult of 3 to 5 cc of curare about the time the skin is incised usually produces maximal relaxation as the peritoneum is opened One or more doses are added intravenously as needed every twenty to thirty minutes for relaxation Ether has a curariform action, and if curare is combined with this agent, smaller doses—about a third—should be used and they must be given with extreme caution A high concentration of curare in a Pentothal solution may precipitate, thus if the two solutions are mixed, there should be an excess of Pentothal

Apart from its value in producing surgical relaxation, curare has been used successfully in the treatment of ether convulsions,¹⁴ laryngospasm⁶ and hiccups It is extremely valuable in the instrumentation or intubation of the pharynx, larynx and trachea

Curare must never be given in the absence of adequately trained personnel and the necessary equipment to provide oxygen for an otherwise helpless patient

THE EXPANDED USEFULNESS OF PENTOTHAL

In 1945 Adams¹⁵ reported the results of the first ten years of administration of Pentothal anesthesia His claims then, and more recently at the Morton

*Obtainable from E. R. Squibb and Sons, New York City

Centennial Celebration in Boston, have been remarkably conservative. He considers Pentothal extremely significant in its supplemental or integrating effect with other agents but of secondary importance when used alone. Many authors, however, report the use of Pentothal as the sole anesthetic agent for almost every conceivable operative procedure. A series of 837 cases in which major elective operations were performed under Pentothal and 100 per cent oxygen included procedures on the gall bladder and common duct in 92, gastric resections in 4 and abdominoperineal resections in 2.¹⁶ The author claims no anesthetic deaths, and only 1.8 per cent major and minor complications. Certainly, this record is beyond the experience of most anesthesiologists. Holly¹⁷ also used Pentothal in a wide variety of cases. He has found, in disagreement with Adams and most other observers, that there is no contraindication in children or even in infants.¹⁸

The abundance of Pentothal technics reported prevents any attempt to list them all even briefly. Some of the articles cover bronchoscopy,¹⁹ goiter surgery,²⁰ tonsillectomy²¹ and oral surgery.²²

There is a trend toward the use of dilute Pentothal solutions in continuous drip.²⁴⁻²⁶ The advantages claimed for this technic are smoother induction and maintenance, less danger of needle blockage, less wastage, less danger of extravasation of concentrated solution and more mechanical freedom for the anesthetist. The disadvantages are slower increase in depth, danger of overdosage and more cumbersome apparatus.

A 20-cc, 30-cc or 50-cc syringe with tubing, adapter, needle and a stopcock to prevent backflow comprises the usual equipment for administering Pentothal. For continuous-flow technics, the Pentothal is manufactured in bulk in 0.25 to 1.0 per cent solution in 5 per cent dextrose and given intravenously at a speed commensurate with the needs of the patient. The bulk solution, if backflows and other contamination are prevented, will keep at least a week at room temperature and will save considerable waste involved in the serial-injection technics. Pentothal solutions should not be used if any precipitate is present. Methods of reducing the dose of Pentothal to lighten the immediate depressant effects, as well as to shorten the postoperative recovery period, are a combination with regional block,^{26,27} local or nitrous oxide anesthesia,²⁷ use of curare or intravenous morphine^{27,28} and cocaineization of the larynx and pharynx.²¹

The contraindications to Pentothal are gradually changing. Shock is no longer an absolute contraindication.^{15,26} Rovenstine et al.^{29,30} have given Pentothal an intermediate place in the anesthesia of shock, with cyclopropane rated "good" and ether "poor." Liver damage, along with kidney damage, has been questioned as an absolute contraindication. Neither the liver nor the kidneys play a primary role in the breakdown of Pentothal.^{31,32} Holly¹⁸ has

invaded the field of pediatric anesthesia with Pentothal and is quite satisfied. The only remaining absolute contraindication to the use of the drug is inability of the anesthetist to maintain concurrently the necessary oxygenation of the patient and the desired depth of anesthesia.

NEW TECHNIQS

Various combinations of curare with inhalation anesthetics,^{13,33} or with Pentothal,⁵ constitute the basis for most of the new technics of general anesthesia. Hathaway and his associates,¹³ for example, have used curare to produce apnea and have maintained unconsciousness with nitrous oxide and oxygen during long periods of controlled respiration.

The new technics depend heavily for their success and safety on the ability of the anesthetist who has, in Drinker's³⁴ words, "had the temerity to become the oxygen supplier of another individual."

From time to time, minor improvements in equipment have appeared, such as vinyl-plastic endotracheal tubes,³⁵ new laryngoscope designs,³⁶ means of bilateral nasoendotracheal administration³⁷ and constant suction for chest surgery.³⁸ These improvements, although collectively important, are so numerous that they must be left to the process of casual discovery.

In most anesthetic procedures success is ensured by proper premedication. Driggs³⁹ has given an over-all view of the rationale. He has analyzed the effects of morphine, the barbiturates and the pressor drugs and has compared scopolamine with atropine.

Premedication is made more flexible by administration in divided doses and by the use of intravenous morphine and atropine. The maximal respiratory depressant effect following the intravenous injection of morphine is obtained in three to seven minutes.⁴⁰ Pearman²⁵ has described a safe technic and commented on the reduced amount of Pentothal following proper use of morphine. Various substitutes for morphine have been suggested to lessen postoperative nausea and vomiting.⁴¹ Handley and Ensberg,⁴² in a study of five respiratory stimulants, report amphetamine to be the most effective in combating respiratory depression following morphine overdosage.

Atropine in large doses — 0.6 mg (1/100 gr) for adults — has been suggested for prophylaxis against laryngospasm.⁴³

Atropine, but not scopolamine, counteracts the barbiturate and morphine effect of lowering the prothrombin time.⁴⁴ These findings have suggestive importance in the prophylaxis of postoperative thrombus formation.

In oral surgery the desirability of complete topical anesthesia of the pharynx and larynx has been emphasized, and the technic described.^{22,23,45}

PHYSIOLOGIC INVESTIGATIONS

Much physiologic research is of direct significance to anesthesiologists. Of this work, however, only a

small fraction — that described in the literature on surgery and anesthesia — is considered below. Even this must be in the form of suggestions for further reading rather than full discussion.

Anoxia

There are still those who condone degrees of anoxia in conjunction with nitrous oxide anesthesia.⁴⁶⁻⁴⁷ This attitude is not shared by most workers,⁴⁸⁻⁵² and the tendency in recent years is to bring the greatest enemy, anoxia, into the open. In their challenging paper, Barach and Rovenstine⁵² review disapprovingly the literature advocating so-called "asphyxia" as an adjunct to nitrous oxide administration and present factual evidence of the death and injury caused by such anoxia. Finally, they protest against the continued use of anesthetic mixtures containing less than 20 per cent oxygen.

Adams et al.⁴⁸ have made interesting measurements of blood oxygen to show that whereas the patient may be well oxygenated during operation, the oxygen concentration may fall to dangerous levels post-operatively. They also point out that high concentrations of oxygen in the anesthetic mixture do not necessarily ensure proper oxygenation, and they have analyzed at length the hindrances to proper oxygenation during intrathoracic operations. These are decreased efficiency of respiratory effect, decreased ventilation of the lung, decreased cardiac output and alteration of the transport mediums.

The work of Courville⁵³ should be read for an understanding of the pathological background to the present attack on anoxia.

Anesthesia of Shock

For the patient who is undergoing severe hemorrhage or who is in shock, cyclopropane is considered by some to be the best general anesthetic agent.²⁸⁻³⁰ After extensive microscopical observations in vivo of the peripheral circulation Rovenstine and his co-workers³⁰ have come to several valuable conclusions. "Ether anesthesia predisposed animals to early and extensive deterioration of the peripheral compensatory mechanisms and decreased their tolerance to hemorrhage and their response to transfusion. Cyclopropane did not produce these effects." They believe that cyclopropane actually improves the condition of many patients following sudden severe hemorrhage.²⁹ Evans,²⁸ although granting that cyclopropane is ideal when available, has properly insisted that other safe technics should be at hand. He has suggested regional block anesthesia and light doses of Pentothal. Gould⁴⁹ apparently still favors ether in many cases. Whatever method is used, massive intravenous therapy, — usually with blood, — minimal amounts of anesthetic, minor surgical procedures and a high concentration of oxygen are essential to success in the anesthesia of shock.

Organization of Intravenous Therapy

Intravenous therapy with particular reference to the surgical patient should be a part of the specialized knowledge of the anesthesiologist. It is a major factor in the prophylactic treatment of surgical shock. New progress has been made in the organization within the hospital for the effective and safe administration of intravenous fluids.⁵⁴

In some hospitals the entire transfusion service has become a function of the anesthesiology department.⁵⁵ In others fluid therapy, including transfusion, is the sole responsibility of the anesthesiologist in the operating room. These responsibilities, complete or limited as they may be, carry with them the need for thorough understanding of a broad physiologic field. A knowledge of the principles of blood grouping and the management of transfusion reactions, as well as an appreciation of water and electrolyte balance and protein requirements, is a prerequisite for the modern anesthesiologist.⁵⁶⁻⁵⁸

Pulmonary Edema and Inflammation

The mechanism and treatment of pulmonary edema have been described in a classic monograph by Drinker.³¹ He has explained on an experimental basis how pulmonary edema is the result of two factors: a sustained increase in the intracapillary pressure of the lungs and a decrease in the oxygen tension of alveolar air.

Early or prophylactic treatment is best. This consists in the administration of 100 per cent oxygen under a positive pressure equivalent to about 10 mm of mercury during both phases of respiration.

Increased Intrapulmonary Pressure

The widespread use of anesthetic technics and therapeutic measures, such as that suggested by Drinker, under increased intrapulmonary pressure has stimulated experimental work on the physiologic effects of such pressure. Beecher et al.⁵⁹ have stated that in animals with poor circulation increased pressure in the airway is deleterious and causes death. On the other hand, Thornton and his associates⁶⁰ have observed that it is of highest importance to the oxygenation of dogs with chest open to maintain a constant endobronchial pressure equivalent to about 8 cm of water. Knoefel et al.⁶¹ have shown that the respiration of dogs under barbitol anesthesia for three hours at a positive pressure equivalent to 7 mm of mercury leads to a 41 per cent reduction of cardiac output, with increased venous pressure and unchanged respiratory volume, oxygen consumption, blood carbon dioxide content and plasma volume. Dogs under similar conditions for one hour may or may not show reduced cardiac output. Further work on this subject is necessary. The investigations of Drinker on pulmonary edema may furnish some valuable clues.

Effect of Ether on the Lower Respiratory Tract

Surprising inferences have been drawn concerning the effect of ether on the output of fluids by the lower respiratory tract.⁶² No change in such secretion was found in the first through the third plane of anesthesia in etherized dogs, cats and rabbits. In addition, since postural drainage did not increase the apparent flow, the conclusion was reached that ciliary action in the lower respiratory tract is not altered by inhaled ether. Atropine sulfate also has no effect in decreasing fluid production in this region. These findings, if corroborated in man, increase the importance of the role of upper-respiratory-tract secretion in the etiology of atelectasis, and cuffed endotracheal tubes may be more frequently indicated.

Atelectasis

A group of simple experiments by Hilding⁶³ have given a probable explanation of the mechanism of atelectasis. In a cylinder of hen trachea considerable negative pressure builds up behind piston-like mucous material moved orally by ciliary action. It is suggested that this piston-like action, and not the absorption of gases trapped behind fixed mucous plugs, is the principal factor producing collapse of distal lung segments.

Laryngospasm

Annoying and frequently dangerous reflexes producing laryngospasm are only moderately well controlled by heavy doses of atropine.⁶⁴ Moreover, once laryngospasm is most frequently encountered during light anesthesia, vomiting and aspiration may precipitate a crisis. A reliable, rapidly acting means of controlling the spasm has been widely sought. Curare is said by some to offer an effective solution.⁶⁵

Effect of New Drugs

The group of drugs represented by propyl thiouracil has reduced the problems of anesthesia for thyroid surgery essentially to those for any other surgical procedure about the neck. With almost no exception, thyroid storms and the heavy doses of anesthetic agents necessary in thyrotoxicosis are part of medical history.

Another group of drugs, represented by penicillin and streptomycin, have reduced postanesthetic morbidity and mortality.

Ether Convulsions

Rosenow, Mousel and Lundv⁶⁶ have reported further investigation in an attempt to establish an etiologic relation between certain streptococci and convulsions under ether anesthesia.

Cyclopropane Arrhythmias

Since the introduction of cyclopropane, two constant objections have plagued the administrator: an

extremely real explosion hazard⁶⁶⁻⁶⁷ and the occurrence of dangerous cardiac arrhythmias.⁶⁸ The explosion hazard has been reduced by the proper training of operating-room personnel, the elimination of materials and machines producing high charges of static electricity, the use of closed technics, the use of the Horton intercoupler and other more debatable measures.⁶⁹

The arrhythmias remain as part of the calculated risk present with this, as it is with any other, anesthetic agent. They vary from premonitory sinus arrhythmia, dropped beats and coupled beats to ventricular fibrillation and cardiac standstill.

Direct cardiac massage and forced respiration are the principal factors in resuscitation.⁷⁰ Recent work by Stutzman et al.⁷¹ indicates that intravenous procaine has no value in restoring normal rhythm once ventricular fibrillation has occurred. Burstein and his associates,⁷²⁻⁷⁴ however, who carried out the original work on the use of procaine, have since presented case reports⁷⁵ to refute the animal experiments of Stutzman. Burstein has used intravenous procaine for cardiac arrhythmias during anesthesia in dosages of 3 to 7 cc of a 1 per cent solution.

Allen et al.⁷⁶ investigated the mechanism of cardiac arrhythmias in cats under cyclopropane anesthesia and decided that, whereas vagal tonus is not essential in the mechanism, cardiac sympathectomy abolishes spontaneous cyclopropane arrhythmias of ventricular origin. They have discussed the danger of sympatheticolytic drugs in practice, however, and have advised dilution of cyclopropane with more oxygen at the onset of cardiac arrhythmias. If this measure is not effective or if the proper level of anesthesia cannot be maintained, they have used a different agent.

Explosion Hazards

The danger of anesthetic explosion has been discussed,⁶⁶⁻⁶⁷ but only one new preventive suggestion has been put forth — the ionization of the air to reduce static electricity accumulations.⁶⁹ This measure appears to be less practicable than the program set forth in the report of the Committee on Static Electricity,⁷⁷ reprinted from the *Quarterly of the National Fire Protective Association*.

Chemical Absorbents of Carbon Dioxide

Following laboratory experiments, Adriani⁷⁸ fixed the ideal characteristics of agents used to absorb carbon dioxide during anesthesia. The optimum water content (between 10 and 22 per cent),⁷⁹ the size of granules (4 to 8 mesh) and other mechanical and chemical variables have been summarized in his new book.⁸⁰ More recently, Mousel, Weiss and Gilliom,⁸¹ after extensive clinical investigation, have favored baralyme as a more satisfactory absorbent for general use.

Electronarcosis

The production of the anesthetic state by electric currents has been known for decades. The method is relatively safe and reversible in the effects noted. Although the phenomenon is still under investigation, it is not yet suited for clinical application.^{82, 83}

Metopryl

The most recent efforts of the Krantz⁸⁴ group to replace ether have resulted in a product called Metopryl. This volatile agent, closely related to di-ethyl ether, was recently proposed, at a meeting of the International College of Anesthetists, as an agent surpassing ether in rapidity of action, freedom from local irritation and surgical relaxation. Confirmation from other workers has not yet been given.

CASE 33221

PRESENTATION OF CASE

First admission. A forty-two-year-old housewife entered the hospital because of vaginal bleeding. The patient had been in excellent health until six months before entry, when she had first noticed slight generalized weakness and easy fatigability. Three months later an unusually prolonged and profuse period had occurred, and she had subsequently had some intermittent intermenstrual bleeding associated with abdominal cramps, gradually increasing in severity. She had also had occasional hot flashes. During the next to the last period, which occurred four weeks before entry, she used ten to fifteen napkins a day and passed some blood clots. Abdominal cramps were again severe, and she had one episode of "cold sweats" and fainting. Since then she bled almost every other day, requiring as many as ten napkins a day. Six days before entry she began to bleed constantly, passing some small clots, and on the day before entry she passed a clot about the size of a fist. During the three days before entry she occasionally had chill sensations and fainted several times. There had been no pain or headaches.

The patient had begun to menstruate at the age of sixteen years, and until the present illness the periods had always been regular, occurring every twenty-six to twenty-eight days and lasting for five or six days. They had always been somewhat

profuse. She had had six children, the eldest of whom was twenty-six years and the youngest fourteen years of age. In the two months before entry she had lost about 10 pounds. She had not had intercourse for eight months before entry.

Physical examination revealed a pale, somewhat obese woman. The heart, lungs and abdomen were normal. There was a slight cystocele and first-degree procidentia. There was a bloody discharge from the cervix. The uterus was about twice the normal size and in third-degree retroversion.

The temperature, pulse and respirations were normal. The blood pressure was 130 systolic, 70 diastolic.

Examination of the blood disclosed a red-cell count of 3,300,000, with 12.0 gm. of hemoglobin, and a white-cell count of 5400, with 60 per cent neutrophils. A blood Hinton test was negative. The urine was normal.

On the third hospital day a total hysterectomy was performed. The cervix was bilaterally ulcerated and contained some small Nabothian cysts. The uterus measured 10 by 4 by 3 cm., and the myometrium was studded with firm, yellowish-orange nodules, 1 or 2 mm. in diameter. The endometrium was reddish orange and 1 mm. thick except at the fundus, where a 1.5-cm. polypoid mass was present. The pathological diagnosis was neurofibromas of the myometrium. The patient recovered uneventfully and was discharged on the seventeenth hospital day.

Second admission (two years later). Following discharge the patient continued to complain of weakness. She also had slight stress incontinence, which was the presenting complaint. The weight had increased from 149 pounds at the time of the first admission to 158 pounds.

The physical findings were essentially unchanged. The hemoglobin was 15.0 gm., and the white-cell count 5400. The urine was normal.

On the fourth hospital day an anterior colporrhaphy and a perineorrhaphy were performed. The postoperative course was uneventful, and the patient was discharged on the fifteenth hospital day.

Third admission (fourteen months later). For several months after the operation the patient was

well and continent of urine. Then, slight incontinence returned. Also, she continued to suffer from weakness and fatigue. Iron pills prescribed by a physician were of no avail. For ten months she had had occasional attacks of nausea and cramps in the "pit of the stomach." These episodes usually came within thirty minutes to an hour following a meal. She had no intolerance to fatty foods. She also complained of increasing constipation and frequent hot flashes and jittery spells lasting about fifteen minutes at a time. She had lost about 10 pounds in weight despite progressive enlargement of the abdomen for several months.

On physical examination the patient appeared chronically ill. The lungs were clear. The abdomen was protuberant and tympanitic. Peristalsis was active. A large, poorly defined, somewhat movable, hard, slightly tender mass filled most of the right lower and middle portions of the abdomen. It was ovoid in shape, with its long axis parallel to the long axis of the body, arose in the pelvis and extended to the umbilicus. A smaller cystic mass was felt in the left pelvis, and there was a mass dissecting down between the vagina and the rectum.

The temperature was 102.5°F, the pulse 120, and the respirations 25. The blood pressure was 120 systolic, 75 diastolic.

Examination of the blood revealed a hemoglobin of 11.2 gm and a white-cell count of 15,500 with 89 per cent neutrophils. The nonprotein nitrogen was 25 mg, and the serum protein 6.7 gm per 100 cc.

The urine gave a ++ test for albumin. The sediment from a catheterized specimen contained 3 red cells and 20 white cells per high-power field. Cultures showed abundant colonies of colon bacilli.

X-ray examination disclosed an area of horizontal linear density in the left lower-lung field. There were a number of rounded, calcified areas with centers of decreased density in the right upper quadrant of the abdomen. A rounded calcified mass, 3 cm in diameter, was present in the left upper quadrant. The kidneys appeared normal in position and size, the right being slightly larger than the left. Both excreted intravenous dye promptly, and the urinary passages on the left appeared normal. There was a marked accumulation of dye in the right kidney two hours after injection and moderate dilatation of the right pelvis, calyces and upper right ureter. Both ureters were displaced laterally by what appeared to be a lobulated mass about 13 cm in diameter in the midpelvis. This compressed the upper border of the bladder. A second, rounded mass about 11 cm in diameter was lying over the upper border of the sacrum on the right. These masses were rather sharply defined, smooth and free of calcification. A barium enema showed no evidence of intrinsic bowel disease.

On the sixth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR PAUL A YOUNGE On the first admission this patient had a cystocele and a first-degree procidentia. There is often confusion between the terms "prolapse" and "procidentia" of the uterus. Procidentia, as we use the term, means that the uterus is outside the introitus.

DR FRANCIS M INGERSOLL I should say that the uterus was moderately prolapsed, it just came down to the introitus.

DR JOE V MEIGS Then this was not a procidentia.

DR YOUNGE I should say, a second-degree prolapse.

Symptoms of cramps with flowing usually mean definite intrauterine lesion, such as pedunculated fibroid or pedunculated adenomyoma. Occasionally with dysfunctional flowing, large clots are passed in association with cramps, but there is not so much intermenstrual bleeding as this patient had. From the history, I think that she had a submucous pedunculated tumor. Another lesion that could cause the symptoms is a carcinoma of the cervix obstructing the cervical canal. This results in pain and intermenstrual bleeding that is perhaps not so profuse as that in the case under discussion. I assume that dilatation and curettage were not done beforehand, since no mention is made of such procedures.

The uterus that was removed is described as measuring 10 by 4 by 3 cm, that fact fails to substantiate the clinical finding of a uterus twice the normal size because the measurements are those of a normal or somewhat small uterus. There was a small intrauterine tumor, which may have caused the symptoms of cramps and bleeding. The gross description sounds like an endometrial polyp, and I am mystified by the pathological diagnosis of neurofibroma of the myometrium. That is a completely new lesion of the uterus so far as I am concerned, and I do not know its significance. It is possible that it was a part of a generalized neurofibromatosis, but there is no confirmatory evidence for such a hypothesis in the history or the physical examination. I also fail to understand why at the first operation nothing was done about the relaxed pelvic floor.

On the third admission the outstanding symptoms were loss of weight, general debility and cramps and nausea after eating. Physical examination disclosed bilateral pelvic masses, one of which extended up into the abdomen. The intravenous pyelogram demonstrated ureteral obstruction on the right. The pelvic tumor that most frequently causes obstruction in the urinary tract is carcinoma of the cervix, and I have considered that diagnosis seriously in spite of the description of the cervix at the time of hysterectomy. The ovaries were not removed at the first operation, and bilateral pelvic tumors and gastrointestinal symptoms such as she had made

one think of a Krukenberg tumor. The ovaries may have developed a primary malignant tumor, but carcinoma of the ovary seldom causes ureteral obstruction. The patient must have had an infiltrating tumor in the broad ligament obstructing the ureter, and we know that she had infiltration of the recto-vaginal septum. This again makes one think of carcinoma of the cervix, but since that is apparently

urinary tract on the right. The barium in the small intestine outlines the soft-tissue mass.

DR YOUNG: I did not realize that there were three pelvic masses.

DR WYMAN: I do not know whether there are three or whether it is one lobulated mass.

DR YOUNG: Since one of the original lesions was a neurofibroma, I suppose that one should consider

FIGURE 1

ruled out, my diagnosis is a Krukenberg tumor of the ovary, bilateral, with metastases in the pelvis causing ureteral obstruction and hydronephrosis. She also had gallstones. I am not certain what to say about the x-ray findings of the lungs—they may have been due to a thick interlobar septum and were probably not due to cancer.

DR STANLEY WYMAN: The area of linear density in the left lower-lung field just above the diaphragm. There may be some collapse of the lower lobe. I think of atelectasis. This plain film of the abdomen, taken on the same day, shows a rounded mass. A second overlying shadow is faintly discernible at this point, and a third round mass overlaps, with some gas apparently flowing around it. The small areas of calcified ringlike density that are seen in the right upper quadrant conform to the configuration of the expected site of the gall bladder. This is the mass of round calcification seen on the left. After the intravenous introduction of dye, the first film shows delay in excretion by the right kidney, presumably due to the obstructed ureter. The film taken two hours after the introduction of dye shows considerable dye remaining in the upper

neurofibrosarcoma. But I know nothing about that. I do not know what to expect benign uterine neurofibromas to be accompanied by or followed by, and I shall omit that as a possibility and stick to the diagnosis of Krukenberg tumor.

DR TRACY B. MALLORY: The diagnosis of neurofibromatosis of the uterus was made during my absence from the laboratory, and I disclaim responsibility. I do not wonder that the pathologist was puzzled by the sections, one of which is shown in Figure 1. This is from the polypoid tumor in the uterine cavity and shows a few widely dispersed endometrial glands separated by exceptionally abundant endometrial stroma. In this stroma were numerous whorls of exceptional cellularity. Similar masses of small spindle cells, also with a tendency to whorl formation, invaded deeply into the myometrium. The pattern resembles that seen in tumors arising from nerve sheaths, but I do not believe that I should have made that diagnosis. I seriously considered the possibility of a granulosa-cell tumor primary in the ovary, but the apparent normality of the ovaries at the first operation made this ex-

tremely improbable I finally decided that an endometrial sarcoma was the best diagnosis

DR YOUNGE Could you exclude leiomyosarcoma or cellular leiomyoma? We have had a recent case of so-called "cellular leiomyoma" in which the patient is dying of metastatic sarcoma. The lesion in the case under discussion may have been a sarcoma.

DR MALLORY I believe that one can rule out leiomyoma or leiomyosarcoma, since these cells are tiny spindle cells, much smaller than muscle cells.

CLINICAL DIAGNOSIS

Carcinoma of ovary?

DR YOUNGE'S DIAGNOSIS

Krukenberg tumor of ovary

ANATOMICAL DIAGNOSIS

Endometrial sarcoma?

Stromal endometriosis (endolymphatic fibromyosis of Frank)?

PATHOLOGICAL DISCUSSION

DR MALLORY Dr Ingersoll, will you tell what you found at operation?

DR INGERSOLL At operation the lower half of the abdomen was studded with a polypoid type of tumor that had infiltrated the omentum and was adherent to the abdominal wall. In the pelvis there were other masses of a similar type of tumor. It was not like any tumor that I had seen before. The omentum and other tissues seemed to be studded with smooth, round masses of varying size. We resected the omentum but were unable to remove the tumor in the pelvis.

DR MEIGS Did you remove the ovaries?

DR INGERSOLL No, the small bowel, the large bowel and everything else were adherent in the pelvis.

DR MEIGS I bring up that point for later discussion in connection with the treatment. It may be important. You did not consciously remove the ovaries?

DR INGERSOLL No.

DR MALLORY The Pathology Department worried over the diagnosis of this case once more for several weeks after the third operation. The probable clue to it, I think, was found, not in the original sections of the uterus, but in the new tumor growth of the omentum. This presented a peculiar appearance—multiple nodules of varying size, some less than a millimeter in diameter, others up to 2 or 3 cm in diameter, of a small spindle-cell neoplasm, which was projecting into and growing in the lumen of spaces lined with endothelium that seemed to be tremendously dilated lymphatic vessels. A characteristic nodule is shown in Figure 2. The tumor corresponds entirely in its histologic appearance to a group of lesions that were reported some years ago by Frank¹ at the Mount Sinai Hos-

pital under the title of "endolymphatic fibromyosis of the uterus." The same tumor has unquestionably been called by other names. I am quite sure that it has been referred to at times as stromal endometriosis, and in certain respects it suggests that

FIGURE 2

condition. We have had a case in the old records of the hospital that Dr Meigs² studied some years ago and illustrated in his book. I suggest that he say something about it.

DR MEIGS When I ran across this tumor in going over the histologic sections in the laboratory, I called it a "leiomyosarcoma invading a fibroid." Dr Goodall³ and later Dr James Miller,⁴ of Hartford, reported a stromal endometrium, having all the characteristics seen in this picture. This picture in my book, which was drawn without knowledge of what it was, demonstrates the small worm-like nodules growing in the lymphatic vessels of the fibroids. Our case was undoubtedly a stromal endometrium invading lymphatic vessels and was similar to Dr Miller's case.

May I ask Dr Ingersoll if x-ray treatment was given? In certain cases of stromal endometriosis, even though the tumor appears extremely malignant, with extensive invasion of the lymphatic vessels, x-ray treatment has been effective, presumably as the result of abolishing ovarian function. If this patient received x-ray treatment, what happened to her?

DR INGERSOLL She was extremely ill throughout her stay in the hospital, and we gave an unfavorable prognosis, not knowing what type of tumor she had. She received a total of 4100 r during a three-week period. When seen in my office four months later she looked well. All the masses have disappeared except the one in the rectovaginal septum.

DR MEIGS That is what Goodall and Miller state that x-ray treatment, not of the tumor but of the gonads, may perform the miracle that seems

to have been performed. This tumor and the one in the book are similar. My patient is also living and well, after a total removal of the genital organs. It looked as if she could not live when one saw the tumor masses, but she did.

DR INGERSOLL: One of the patients in Frank's original cases responded well to x-ray treatment. The tumor had been incompletely removed, and following operation the patient received x-ray treatment and survived for a long time.

CASE 33222

PRESENTATION OF CASE

A fifty-year-old unmarried, retired schoolteacher was admitted to the hospital because of abdominal cramps and distention.

For twenty-five years the patient had had recurrent, transient gastrointestinal upsets, occurring on an average of two or three times a year and lasting two or three hours. The episodes were characterized by pain and gas in the upper abdomen, nausea, vomiting and diarrhea. About two years before entry x-ray studies — apparently, a gastrointestinal series and a barium enema — were said to have been negative. For the five months immediately preceding entry she had noticed a gradual but definite change in symptoms, with increasing, audible borborygmi and shifting "lumps of gas" in the abdomen. She had had occasional cramping periumbilical pain, with nausea and vomiting, and intermittent alternating constipation and diarrhea. She denied having noted hematemesis, tenesmus, bleeding by rectum or black, tarry stools. The stools had often been light, almost white, but she had never been jaundiced or noticed dark urine. She had had no chills or fever. Fatty foods always caused some dyspepsia. Four nights before entry she had awakened in the middle of the night with a particularly severe attack of abdominal cramps and diffuse pain. A gastrointestinal series and barium enema in another hospital revealed something "down low in the small bowel that required operation very soon." She had taken practically nothing by mouth on the day of entry and had had two small watery movements without gas. She admitted a weight loss of undetermined amount in the preceding four months.

A thyroidectomy had been performed twenty years previously. The patient stated that her mother and a maternal aunt had died of cancer and that one of her sisters was seriously ill with cancer

of the breast. One sibling had died of tuberculosis.

Physical examination revealed a thin, pale, somewhat dehydrated woman in no acute discomfort. The abdomen was distended and tympanitic. There was visible, audible and palpable peristalsis, with rushes, high-pitched tinkles and fluid gurglings of the distended loops of bowel. There was moderate tenderness without spasm in the lower abdomen in the midline, but no masses. The examination was unsatisfactory, however, because of the distention.

The temperature, pulse and respirations were normal. The blood pressure was 120 systolic, 70 diastolic.

The white-cell count was 8500, with a normal differential. The hemoglobin was 11.4 gm, and the hematocrit 36. The urine was normal. The nonprotein nitrogen was 23 mg, and the total protein 5.6 gm per 100 cc. The chloride was 101 milliequiv, and the carbon dioxide 25.4 milliequiv per liter. X-ray examination was not repeated in this hospital.

During the first week in the hospital decompression of the small-bowel distention with a Harris tube was effected. By the fifth hospital day the tube lay over the sacrum and was apparently fairly close to the point of obstruction. The patient was given 2500 to 4000 cc of intravenous fluids a day including Amigen, dextrose, physiologic saline solution and vitamins, and four transfusions were administered.

On the eighth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR ARTHUR W. ALLEN: The record states that no x-ray studies were done in this hospital. Do we have the films taken outside?

DR LAURENCE L. ROBBINS: No, but I can help you a little by describing them. I have brought along a film that shows an essentially similar appearance. Here is a single dilated loop of small bowel that appears to arch around something, as if it might partially surround a tumor mass. The dilated segment of bowel terminates with a shelf-like margin, and distal to this point the bowel is relatively collapsed. That is as close as I can come to describing the x-ray appearance. The dilated loop was demonstrated in two films taken some time apart, and its appearance remained essentially unchanged. The fluoroscopist believed that he could localize the obstruction in the lower small bowel.

DR ALLEN: I was certain that a film of the abdomen had been taken on admission so that we could see to what extent the loops of small intestine had become dilated. I suppose that without the slightest doubt we must accept the fact that she had small-bowel obstruction, which was low in the ileum.

The past history is interesting. It is difficult for me to see how we can account for the episodes of gastrointestinal difficulties lasting only two or

tremely improbable I finally decided that an endometrial sarcoma was the best diagnosis

DR YOUNGE Could you exclude leiomyosarcoma or cellular leiomyoma? We have had a recent case of so-called "cellular leiomyoma" in which the patient is dying of metastatic sarcoma. The lesion in the case under discussion may have been a sarcoma.

DR MALLORY I believe that one can rule out leiomyoma or leiomyosarcoma, since these cells are tiny spindle cells, much smaller than muscle cells.

CLINICAL DIAGNOSIS

Carcinoma of ovary?

DR YOUNGE'S DIAGNOSIS

Krukenberg tumor of ovary

ANATOMICAL DIAGNOSIS

Endometrial sarcoma?

Stromal endometriosis (endolymphatic fibromyosis of Frank)?

PATHOLOGICAL DISCUSSION

DR MALLORY Dr Ingersoll, will you tell what you found at operation?

DR INGERSOLL At operation the lower half of the abdomen was studded with a polypoid type of tumor that had infiltrated the omentum and was adherent to the abdominal wall. In the pelvis there were other masses of a similar type of tumor. It was not like any tumor that I had seen before. The omentum and other tissues seemed to be studded with smooth, round masses of varying size. We resected the omentum but were unable to remove the tumor in the pelvis.

DR MEIGS Did you remove the ovaries?

DR INGERSOLL No, the small bowel, the large bowel and everything else were adherent in the pelvis.

DR MEIGS I bring up that point for later discussion in connection with the treatment. It may be important. You did not consciously remove the ovaries?

DR INGERSOLL No.

DR MALLORY The Pathology Department worried over the diagnosis of this case once more for several weeks after the third operation. The probable clue to it, I think, was found, not in the original sections of the uterus, but in the new tumor growth of the omentum. This presented a peculiar appearance—multiple nodules of varying size, some less than a millimeter in diameter, others up to 2 or 3 cm in diameter, of a small spindle-cell neoplasm, which was projecting into and growing in the lumen of spaces lined with endothelium that seemed to be tremendously dilated lymphatic vessels. A characteristic nodule is shown in Figure 2. The tumor corresponds entirely in its histologic appearance to a group of lesions that were reported some years ago by Frank¹ at the Mount Sinai Hos-

pital under the title of "endolymphatic fibromyosis of the uterus." The same tumor has unquestionably been called by other names. I am quite sure that it has been referred to at times as stromal endometriosis, and in certain respects it suggests the

FIGURE 2

condition. We have had a case in the old records of the hospital that Dr Meigs² studied some years ago and illustrated in his book. I suggest that he say something about it.

DR MEIGS When I ran across this tumor in going over the histologic sections in the laboratory, I called it a "leiomyosarcoma invading a fibroid." Dr Goodall³ and later Dr James Miller,⁴ of Hartford, reported a stromal endometrium, having all the characteristics seen in this picture. This picture in my book, which was drawn without knowledge of what it was, demonstrates the small worm-like nodules growing in the lymphatic vessels of the fibroids. Our case was undoubtedly a stromal endometrium invading lymphatic vessels and was similar to Dr Miller's case.

May I ask Dr Ingersoll if x-ray treatment was given? In certain cases of stromal endometriosis, even though the tumor appears extremely malignant, with extensive invasion of the lymphatic vessels, x-ray treatment has been effective, presumably as the result of abolishing ovarian function. If this patient received x-ray treatment, what happened to her?

DR INGERSOLL She was extremely ill throughout her stay in the hospital, and we gave an unfavorable prognosis, not knowing what type of tumor she had. She received a total of 4100 r during a three-week period. When seen in my office four months later she looked well. All the masses have disappeared except the one in the rectovaginal septum.

DR MEIGS That is what Goodall and Miller state that x-ray treatment, not of the tumor but of the gonads, may perform the miracle that seems-

Dr ALLEN I think that it is reasonable to consider the case in that light. I hesitate only because tuberculosis involving the small intestine is extremely rare. It usually occurs in the cecum. The cecum may have been involved, but we have no evidence that it was. I think that Dr Robbins would have been able to help more if it had been. Certainly, after the distention had been relieved, a mass should have been palpable in the right lower quadrant. I suppose it is possible for regional ileitis to be present for twenty-five years with extremely few symptoms. I have never seen such a case. The patients I have seen have always had a shorter history or an earlier onset.

Dr. BAUER The patient was so far removed from the onset of the acute attack that she may not have remembered the details.

The character of the stools described made me wonder if we should consider an infectious disease of the small intestine. The stool was white. The patient was never jaundiced and never had dark urine. I should hold out for chronic steatorrhea due to an extensive lesion of the small intestine, such as regional ileitis or tuberculosis.

Dr ROBBINS There was good barium filling of the entire small bowel, and I think that more would have shown in the films if the trouble had been a deficiency state or chronic steatorrhea. The area of narrowing was quite small, which is against regional ileitis. As for the hyperplastic form of tuberculosis, we could not exclude it, but the location is unusual. This was definitely in the ileum, far from the cecum.

Dr. BAUER My only point is that we often get into difficulty and make diagnostic mistakes because we throw away a history and start at a more recent point—in this case five months before admission. A history that goes back twenty-five years is not unlike that in the present case, except for a difference in severity, and I wonder if, because we can find no explanation, we have the right to say that the patient was neurotic.

Dr. NORMAN WILSON I do not believe that we can ignore the history in this case, furthermore, the patient was not neurotic. We carefully considered that possibility. She was an intelligent woman, and the history was a definite one of

trouble that went back twenty-five years but with exaggeration of symptoms for five months before admission. I think that we can accept the history as being all right. The episodes were definite, and between them she was relatively free from symptoms.

Dr ALLEN That bears out Dr Bauer's important criticism of my deduction.

CLINICAL DIAGNOSIS

Small-bowel obstruction, due to long-standing regional ileitis

Dr ALLEN'S DIAGNOSIS

Small-bowel obstruction, due to tumor of terminal ileum, probably malignant

ANATOMICAL DIAGNOSIS

Multiple carcinoids of ileum, with metastases to mesenteric lymph node

PATHOLOGICAL DISCUSSION

Dr TRACY B MALLORY At operation a constricting lesion was found in the small bowel near the terminal ileum. In the mesentery, immediately adjacent to this, was a large, firm metastasis. A short distance away from the first lesion was a second tumor of the ileum. The cut surfaces of the tumors showed small yellow speckles. The larger tumor produced a constriction of the bowel with dilatation of the proximal portion to three times the normal diameter. Despite the dilatation, the wall above the constriction was markedly thickened, so that it is evident that there had been obstruction for a long time. The tumor was composed of extremely small cells containing argentaffin granules, a so-called "carcinoid" of the small bowel. These tumors usually grow extremely slowly. They are invasive and metastasize to regional lymph nodes but do not usually extend beyond them. There is a case in the hospital records in which the bowel was resected, and metastasis to the mesenteric nodes was noted at the time of operation. When the patient died in this hospital sixteen years later of pneumonia, the metastatic carcinoid was found in the mesentery, but it had not spread a centimeter from the original location in all that time.

three hours at a time and occurring two or three times a year for a period of twenty-five years. I think that that type of history might be elicited from a great many schoolteachers of similar age. Perhaps it is unfair to make that classification, but schoolteachers probably have many things to worry about that other people avoid. For five months there had been a definite change in the pattern.

For some reason or other the patient had retired. The age is fairly young for a schoolteacher to stop working, but perhaps it was for reasons other than health, although it is possible that she became more uncomfortable and had to stop working. At any rate, for five months, there were symptoms that may provide a starting point as a present history.

The emphasis on the fact that fatty foods caused dyspepsia, as stated in the record, is interesting but may not have too much bearing on this case, although one must consider the possibility of a gallstone ileus with small-bowel obstruction. The history is not consistent with a gallstone ileus, in that for three or four weeks there should have been fairly acute symptoms simulating acute cholecystitis and preceding the onset of small-bowel obstruction while the fistula was being formed naturally through which the stone would eventually pass into the intestinal tract to become lodged in the terminal ileum at its narrowest point. These patients usually appear in the hospital about forty-eight hours after the onset of obstruction, and as a rule the small bowel is tremendously distended with gas.

Another cause of small-bowel obstruction that must be considered is a foreign body of some type. There are many causes. People swallow enormous boluses of food. A complete orange in two parts may join itself together in the terminal ileum, as we have seen, and cause obstruction. In certain regions of the country there are various forms of bezoar, particularly in the South, where persimmons are eaten, apparently, the fibers get together and cause a bolus that in turn causes intestinal obstruction. Any foreign body, such as a toothpick, may penetrate one wall of the intestine and go into the other and produce the same result.

The most frequent cause of intestinal obstruction in the small bowel is an adhesive band, which often occurs without previous surgery. The patients are liable to be sicker than this patient was, with a high white-cell count, indicating the possibility of gangrene in the bowel and so forth. Usually, there is not a four-day history of acute symptoms prior to entry. I think that we can rule out adhesive bands. Possibly, we cannot rule out torsion of the bowel, which does occur, although not so often in the small intestine as in the large bowel.

The possibility of a Meckel's diverticulum must always be considered in the discussion of intestinal obstruction. This woman gave no indication that she had such a lesion. Although the preoperative

diagnosis is apt to be intestinal obstruction associated with an inflammatory diverticulum, in adults we have the same inflammatory reactions that we have in acute appendicitis, with a high leukocyte count, a mass and a much sicker patient than this woman appeared to be. Intussusception can practically be ruled out on the basis that there was no blood and that the patient is said to have passed two water discharges from the rectum. The fact is stressed that no blood was found.

The nonspecific granulomas, regional ileitis and so forth develop in a slow fashion. They rarely precede an acute situation such as this, unless there is perforation with abscess formation, and there is no indication of that. I believe that Crohn's disease, or terminal ileitis, must be considered in the differential diagnosis, but it is not probable. Two factors in the family history were stressed: a history of cancer in the mother, a maternal aunt and sister, and a death from tuberculosis in a brother or sister. The possibility of a malignant tumor of the small intestine is reasonable, although it is a rare condition — the incidence is so limited that one hesitates to make such a diagnosis. One should be extremely cautious in coming to that conclusion although I must admit that on thinking this case over before I had about decided that I was going to make such a diagnosis. Benign tumors of the intestine are far more frequent. They are, however, usually associated with intussusception. I am not able to read Dr. Robbins's thoughts or to grasp the lead that he tried to give me about the mass underneath this arch of bowel that he has described, and I must say that his efforts do not help me too much.

Having gone through all the various possibilities, I fall back on that of a tumor of the small intestine that had been troublesome for four or five months and that had finally, four days prior to admission, produced an acute obstruction, and I shall therefore make a diagnosis of tumor of the ileum. Incidentally, the farther down the small bowel, the likelier the tumor is to be sarcomatous, the higher up, the likelier it is to be cancer. I do not believe that I want to make a differential diagnosis between adenocarcinoma and sarcoma — or lymphoma, for that matter, there is no evidence of bleeding, however, which is against a carcinoma and in favor of the other type.

DR. WALTER BAUER: I wonder if Dr. Allen is justified in throwing out the history of twenty-five years' duration. I also wonder if one should not entertain the possibility that steatorrhea produced large granulomatous lesions, or one of the infectious granulomas that Dr. Allen has mentioned, such as tuberculosis or regional ileitis. I do not see why that should not fit the whole picture, without the necessity of considering a neoplasm. It would explain all the symptoms and also enable one to account for the difference or increase in symptomatology during the last five months.

thiazole and sulfapyridine, although it may appreciably increase the solubility of sulfadiazine and its derivatives. It also tends to increase the excretion of the latter in the urine, thus partly defeating its purpose. Moreover, the forcing of fluids and the use of alkalis are contraindicated in patients with cardiac or renal insufficiency and also in those with impaired liver function.

These considerations have led to attempts to utilize mixtures of different sulfonamides¹⁻⁵. The rationale for the use of sulfonamide mixtures is based on solubility experiments with combinations of the various effective sulfanilamide derivatives, they showed that if two or more of these compounds are present simultaneously in water or urine, each retains its own solubility, uninfluenced by the presence of the other. In other words, a saturated aqueous or urinary solution of sulfathiazole can still be fully saturated with sulfadiazine and sulfamerazine.²

Lehr¹ used sulfathiazole and sulfadiazine in equal amounts and showed experimentally that this combination produces a low renal toxicity and has a high antibacterial activity. Clinical studies in patients with acute bacterial infection in both adults² and children³ indicated that this mixture given in the total doses ordinarily employed with single compounds yielded uniformly satisfactory therapeutic results. Effective blood levels and high sulfonamide concentrations in the urine were readily maintained with these doses. When treatment was stopped, the mixtures were rapidly cleared from the body. Crystalluria was infrequent despite the intentional omission of adjuvant alkali therapy, and no signs of renal irritation were encountered. The incidence of allergic reactions, moreover, also appeared to be lowered. Similarly, Flippin and his associates⁴ used a mixture containing equal parts of sulfadiazine and sulfamerazine, and they noted that the use of this combination resulted in a markedly decreased incidence of crystalluria compared with that observed when either compound was administered singly.

Extensive studies with sulfonamide mixtures ("sulfa-combinations") have also been carried out by Frisk and his co-workers^{5, 6} in Stockholm. They found that the antibacterial effect of such a com-

bination was equal to the sum of those of the individual components. Their studies showed that when sulfathiazole, sulfadiazine and sulfamerazine were used together each retained its own solubility in buffered solutions or in urine over the usual pH range. The same was true of the acetyl derivatives of these compounds. Experiments in rabbits with these compounds given individually and in combination showed that fewer concretions resulted from the mixture than from any of the individual compounds used separately in equal doses. In human beings the three sulfonamides given simultaneously were found to be absorbed, excreted and acetylated independently.

The most suitable composition per gram was found experimentally to be 0.37 gm of sulfathiazole, 0.37 gm of sulfadiazine and 0.26 gm of sulfamerazine. This mixture had almost the same absorption and excretion relations as sulfadiazine. There was practically no risk from accumulation in the blood, even when high doses were administered. In the doses ordinarily used in the treatment of pneumonia, the combined preparation is not excreted in supersaturated solutions if the reaction of the urine is approximately neutral. With the individual components given in equal doses, on the other hand, either the free or acetylated form always occurs in the urine in supersaturated solution, even in a neutral urine. The Swedish workers thought that the use of this mixture appeared to eliminate the risk of the formation of concretions in normal kidneys. As added precautionary measures, however, they state that diuresis should be maintained and that alkalis should be given. This method is considered to have the advantage of permitting the use of larger doses than usual with less danger of renal complications in cases of infection due to the more resistant bacteria.

So far as the development of sensitization is concerned, a combination of the related compounds sulfadiazine and sulfamerazine appears to be preferable to a combination of sulfathiazole and sulfadiazine. In the former, the two compounds differ only by a single methyl group, sulfamerazine being the monomethyl derivative of sulfadiazine. When used alone, if sensitization to one of these compounds develops it is almost invariably accom-

A M A CENTENNIAL

ONE hundred years ago the American Medical Association had its inception, and although little of great import was accomplished during the first fifty years of its existence, it has made many significant contributions to the advance of medicine during the past fifty years. Among others, these include improved standards for medical schools and hospitals, investigation of quacks and charlatans, approval of drugs, foods and apparatus, professional and lay education, promotion of industrial and rural health and investigation of matters pertaining to the economic aspects of medical practice. Those who were unfamiliar with these achievements must have been made duly conscious by the series of articles covering the history of the Association that

recently appeared in the *Journal of the American Medical Association*, from the pen of its editor, Dr. Morris Fishbein.

The *Journal* extends heartiest congratulations to the Association on the occasion of its hundredth anniversary. No doubt the celebration in Atlantic City will be an event whose memory those who attend will cherish for many years to come.

PREVENTION OF RENAL COMPLICATIONS BY THE USE OF SULFONAMIDE MIXTURES

PENICILLIN, because of its high therapeutic efficacy coupled with its low toxicity, has probably displaced the sulfonamide drugs in the treatment of many types of infection. Streptomycin, likewise, has proved highly effective in a number of other types of infection, for some of which the sulfonamides had previously been used with varying degrees of success. There are still numerous infections, however, for which the sulfonamide drugs continue to be useful and even essential, either alone or as an adjunct to other therapy, and this will probably remain true for some time to come.

Among the most frequent of the serious complications attending the use of the more effective sulfonamide compounds are those involving the urinary tract. These are caused predominantly by mechanical factors associated with the precipitation of crystals of the free or acetylated drugs anywhere along the urinary tract, and they are most serious when the precipitation occurs within the kidney tubules. These complications are dependent, in turn, largely on the solubility and the concentration of the compounds in the urine. Any measures that increase their solubility or prevent their excessive concentrations in the urine should therefore diminish the frequency with which precipitation occurs and hence reduce the incidence of renal complications.

The methods generally employed for this purpose are the forcing of fluids, with a view to producing a more dilute solution, and alkalization of the urine, for the purpose of increasing the solubility of the drugs as they are excreted. These methods have not always brought about the desired effects. Furthermore, alkalization does not markedly affect the solubility of some compounds, notably sulfa-

manently injured, and even distorted, in the school room, in consequence of the neglect of the proper authorities to furnish chairs. Thanks to an enlightened age and the progress of common sense in our city, seats have been introduced at last, properly constructed — An impulse is likely to be given to a much neglected subject, by the energy of the Mass Agricultural Society. On Friday evening, April 16th, a lecture was given in the hall of the House of Representatives, in this city, by Dr Warren, on the general anatomy of the horse. We cheerfully accord to him the honor of having opened a sealed volume in Massachusetts, and thank him, too, in the name of humanity, for this kind effort to lessen the sufferings of this noble and useful animal — On Wednesday last, according to previous arrangements, the National Medical Convention assembled in Philadelphia at an early hour, and organized for the despatch of business. The manner in which the delegates were received by the medical profession of Philadelphia was exceedingly cordial and gratifying. The Convention held its daily sessions in the elegant hall belonging to the Academy of Natural Sciences, located on Broad street. A series of hospitalities characterized the intercourse of the representatives with the medical gentlemen of Philadelphia, which will not soon be forgotten by the former. Dr Stewart, of New York, offered the following resolution on the final day: "Resolved, That all unfinished business be referred to the American Medical Association about to be organized. Resolved, That the Convention do now resolve itself into the 'American Medical Association' and that the officers of the Convention continue to act as officers of the Association until others are appointed." Agreed to — Extracted from the *Boston Medical and Surgical Journal*, April and May, 1847.

NEW HAMPSHIRE MEDICAL SOCIETY

DEATH

BLACK — James S. Black, M.D., of Nashua, died April 21. He was in his seventy-third year. Dr. Black received his degree from Dartmouth Medical School in 1901. He was a fellow of the American College of Surgeons. His widow and a daughter survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

NEW APPOINTMENTS

Robert E. S. Kelley, M.D., a retired captain of the Regular Medical Corps of the United States Navy, has been appointed to the Division of Biologic Laboratories as physician in charge of the second mobile unit of the State Blood Donor Pro-

gram. During more than twenty-nine years in the Navy, Dr. Kelley served as public-health officer of Guam and was loaned to the Republic of Haiti for public-health work for over two years.

Walter J. Pennell, M.D., who retired from the Navy with the rank of captain after nearly thirty years' service in the Medical Corps, has been appointed health officer of the Northeastern District of the Massachusetts Department of Public Health. During his Navy career, Dr. Pennell served as medical officer in command of naval hospitals at Trinidad, British West Indies, Parris Island, South Carolina, and Newport, Rhode Island. He also served as executive officer and consultant in internal medicine and lecturer in cardiology, Navy Medical School. He is a diplomate of the American Board of Internal Medicine.

Paul Richmond, M.D., formerly a captain in the Medical Corps of the United States Navy, has been appointed health officer of the Worcester district of the Massachusetts Department of Public Health. A medical officer in the Navy since 1915, Dr. Richmond served overseas in New Guinea, Australia and the Philippine Islands.

Mary Carr Baker, A.B., has been appointed personnel training co-ordinator of the Massachusetts Department of Public Health. Mrs. Baker will direct in-service training programs and co-ordinate the teaching programs of professional schools, organizations and other agencies participating in public-health teaching. Mrs. Baker was formerly field-program supervisor of the Massachusetts Blood Donor Program.

Robert G. Benson has been appointed field-program supervisor of the Blood Donor Service of the Massachusetts Department of Public Health. Mr. Benson will represent the Department in collaborative activities with the American Red Cross and community organizations and in arranging for local participation in the blood donor program. Mr. Benson has wide field experience, having served for sixteen years as a food and drug inspector with the Massachusetts Department of Public Health.

CONSULTATION CLINICS FOR CRIPPLED CHILDREN IN MASSACHUSETTS UNDER THE PROVISIONS OF THE SOCIAL SECURITY ACT

Worcester	June 20	John W. O'Meara
Fall River	June 23	David S. Grice
Hyannis	June 26	Paul L. Norton

Physicians referring new patients to clinics should get in touch with the district health officer to make appointments.

panied by sensitization to the other, hence, there is no added disadvantage from using both at the same time, and if the patient becomes sensitized, sulfathiazole can be safely used in 85 per cent of the cases. The combination of sulfathiazole and sulfadiazine, on the other hand, would probably result in sensitization to both, and no one of the three drugs could then be given without a reaction.

A HUNDRED YEARS AGO

The trustees of the Massachusetts General Hospital and the McLean Asylum present for the last year an exceedingly favorable report of these institutions. In both the income has exceeded the expenditures, leaving a balance to be appropriated for increased comforts and advantages. One who visits the Allen St. Hospital cannot fail to be struck with the neatness with which wards have been finished and the conveniences with which they are furnished. — The practitioner of medicine has a stomach to be filled, a body to be clothed, and in most cases a family to maintain. To do so, there must be an adequate income from some source to meet the expense of being a part and parcel of the general population. But very few medical practitioners, in this country, begin life with property, those who have that advantage rarely trouble themselves about the details of practice — unless it is for the purpose of maintaining a family position. Physicians are not as successful in the gathering up of property as gentlemen of the law, merchants, or active, bold, operating mechanics. The fees of lawyers are regulated either by special law, bar rules, or custom, in a manner that secures to them every fraction of their dues. Merchants and mechanics most generally, in their bargains, both require and give security, without giving offense, but the physician goes wherever called, not knowing whether he is to be paid or not. His losses, therefore, are immense in the course of a life of medium length. His capital is earning nothing unless he renders a personal service. Every physician is satisfied that one half of his practice, at least, is utterly lost, and per-

haps more. The vulgar impression that the practice of medicine is a profitable business is not true with the mass of the profession, the number of physicians who have made themselves rich in legitimate practice is so small, as hardly to be recognized either in town or country. — Valuable as the Boston Lying-in Hospital proves to be, its locality is exceedingly objectionable, and some effort should be made to bring it down into the heart of the city, where it should have been placed at first. The land might be sold to good advantage, and the money expended equally advantageously in the purchase of a large, convenient house nearer to the center of population. As the patients are not on charity, but pay a small fee, probably the number would be quadrupled were the establishment down in town. It would also better accommodate the directors, the physicians, and every person, in fact, who has any connection with it. — We learn that the Corporation of Harvard University, since the resignation of Dr. Warren, have appointed three new professors, two of whom are to be attached to the Massachusetts Medical College in Boston, and one to the University at Cambridge. The new incumbents are, Oliver W. Holmes, M.D., Professor of Anatomy and Physiology (this is called the Parkman Professorship of Anatomy and Physiology in honor of Dr. George Parkman, a distinguished benefactor of the Medical School), John B. S. Jackson, M.D., Professor of Pathological Anatomy and Curator, and Jeffries Wyman, M.D., Hersey Professor of Anatomy at Cambridge. All the above gentlemen are well known to the public as working men, who by their own talents and persevering industry, have raised themselves to the head of the department in science which they are respectively to teach. We are gratified that the choice of the Corporation has fallen on candidates in whose favor we believe the general suffrage of the medical profession in Massachusetts would have cordially united. — The Philadelphia Medical Examiner believes it is now ascertained by numerous experiments, that sulphuric ether alone possesses the virtues claimed for the "letheon" or "compound gas." Since it is generally conceded both in this country and Europe, that the patent is invalid so the repugnance felt towards any extended notice of the matter is removed, and the Examiner will from time to time notice the experiments and observations made in various parts of the world, confirmatory or otherwise of the good effects of this extraordinary agent. — Through the unwearied exertions of Joseph W. Ingraham, Esq., an efficient member of the Boston Primary School Committee, chairs have been introduced into our public schools for children. Strange, with the foresight and characteristic wisdom of our Puritan forefathers, that they should have overlooked the comfort of a school seat with a back. Certain it is that backs, bones and limbs have more or less been per-

Here is one of a projected series entitled *Monographs on Progress of Research in Holland*. It should be in every reference medical collection.

Cardan. By James Eckman. 4° paper. 120 pp. Baltimore: Johns Hopkins Press, 1946. \$2.00.

During the Renaissance and for an additional period of over a hundred years the University of Padua numbered among its students and professors such great persons as Thomas Linacre, Vesalius, Copernicus, Georgius Agricola, William Harvey, Galileo, and many others including Cardan. The author has made an analytical study of the life and time of Cardan—physician, mathematician and scientist—based on his works and on the mass of writings of the commentators. Cardan, no unfavorable testimony has been suppressed. Cardan—of three hundred and thirty-five references cited in the book concludes the work. Although the works of Cardan are cited throughout the text, it is to be regretted that a bibliography of his published writings was not included in the dissertation. The great and now scarce *Opera*, published in ten volumes at Lyon in 1663, should be in all large medical history collections. Likewise, this analytical dissertation by Eckman should be in all medical-history collections.

History of agency of health service. By Malcolm W. Carr. D.S. Studies of the New York Academy of Medicine. Committee on Medicine and the Changing Order. 8°, cloth. 1 pp. New York: The Commonwealth Fund, 1946. \$1.50. This monograph presents a comprehensive picture of dentistry in the United States including its history and development, present activities and problems and some indications of future trends. The work is divided into six parts: history, education, practice, research, socioeconomic aspects, a summary and conclusions. A short preliminary chapter devoted to the present status of organized dentistry. The part on history covers the period from ancient Egypt to the present time with emphasis on American accomplishments. Education is discussed under the topics of pre-dental education, curriculum, graduate education and hospital relationships and residencies. Dental practice is divided into three in general, including the hygienist, the assistant and laboratory technician, licensure and control and specialization, hospital service, dentistry in industry, public-health dentistry, dentistry in rural areas, dentistry for Negroes, denture dentistry, and national dental legislation. The section on public-health dentistry, which discusses dentistry in public schools, is too short and sketchy and could have been filled with benefit to all persons interested in this phase of the health service. The material is logically arranged but the treatment is uneven and somewhat sketchy in parts. Likewise, the list of references appended to the topics are uneven in distribution giving the impression that portions of the literature have been inadequately covered. The monograph should prove useful to all interested persons, however, and should be in all libraries as a reference source.

Testing Techniques of manual examination. By W. Daniels, M.A., Marian Williams, M.A., and Catherine Whittingham, M.A. 4°, paper, 189 pp. Designed and illustrated by Harold Black with 349 diagrammatic line drawings. Philadelphia and London: W. B. Saunders Company, 1946. \$2.50.

Students, physical therapists and physicians interested in manual medicine, orthopedics and neurology will find this a useful reference and valuable teaching aid. Noteworthy features are the numerous and excellent drawings of the organization of the material. In addition to clear explanations of the technique of manual strength tests of all the muscles there is assembled on the same page the normal range of joint motion, the origin and insertion of the muscles, with anatomical diagrams and the innervation of peripheral nerves and spinal-cord segments.

Complete Handbook on State Medicine. By J. Weston Welch. Paper, 170 pp. Portland, Maine: J. Weston Welch, 1946.

The national high-school debating topic for the school 1946-1947 is state medicine defined as medicine sup-

ported by federal, state or local government. This handbook is primarily designed for high-school debaters and covers both sides of the question. The general and medical literature on the subject has been examined and three hundred and forty-seven quotations for the affirmative and three hundred and forty-four for the negative comprise a large part of the text. The preliminary chapters discuss the question in general including the history of medical plans in the United States and abroad. Although the author believes that a bill similar to the Murray-Wagner-Dingell Bill will not be passed by the next Congress, such matters will prove to be of great concern to the medical profession when the next economic depression occurs unless voluntary medical plans become prevalent before that time. Mr. Welch is well known in educational circles having written debate handbooks on the national and college debate questions since 1926. The material is well organized for its purpose and should prove of value to all medical libraries and physicians and other persons interested in the subject since it provides six hundred and ninety-one direct references to the topic.

Injury and Death under Workmen's Compensation Laws. By Samuel B. Horowitz. 1 B. LI. B. Second printing. 8°, cloth. 486 pp. Boston: Wright and Potter Printing Company, 1946. \$6.00.

The first printing in September 1944 of this authoritative treatise on workmen's compensation was exhausted early necessitating this second printing. The work is divided into four parts. The first, third and fourth deal with the historical and legal aspects of the subject. The second part—on personal injury by accident arising out of and in the course of employment—should prove valuable to all physicians and surgeons who come into contact with cases of injury and compensable diseases. This book should be in all medical libraries and in the libraries of surgeon and physicians interested in the subject.

BOOKS RECEIVED

The receipt of the following books is acknowledged and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Demonstrations of Physical Signs in Clinical Surgery. By Hamilton Bailey, F.R.C.S. (Eng.) F.I.C.S. Surgeon, Royal Northern Hospital, London; surgeon and urologist, County Hospital, Chatham; and senior surgeon, St. Vincent's Clinic and Italian Hospital. Tenth edition, revised. 8°, cloth. 375 pp. with 573 illustrations. Baltimore: Williams and Wilkins Company, 1946. \$7.00. Printed in Great Britain.

This excellent manual first published in 1927 has enjoyed a great popularity. Ten editions and seven reprints have so far been necessary. The book has been translated into Spanish and Portuguese and Italian and Greek translations are in active preparation. The manual has been thoroughly revised and is intended for the use of students and interns. The material is well arranged, and the text well printed with a good readable type on good paper. The illustrations are excellent. An adequate index concludes the volume. The price seems excessive.

Health Instructor Yearbook, 1946. Compiled by Oliver E. Byrd, Ed.D., associate professor of hygiene, Stanford University. 8°, cloth. 599 pp. Stanford University: Stanford University Press, 1946. \$5.00.

This volume is the fourth of a series first published in 1943. It comprises abstracts of three hundred and eighty-four articles appearing in the current literature. The compiler in assembling the abstracts read fifteen hundred and twelve articles in various scientific, medical, statistical and public-health journals. The material covers the whole field of public health in its various aspects and a new chapter on international health has been added to this issue. The abstracts are numbered, and a complete list of references as well as author and subject indexes is appended to the text. The abstracting is well done, and the book well printed.

COMMUNICABLE DISEASES IN MASSACHUSETTS FOR APRIL, 1947

RÉSUMÉ

DISEASES	APRIL 1947	APRIL 1946	SEVEN YEAR MEDIAN
Chancroid	3	2	2*
Chicken pox	2657	1751	1286
Diphtheria	46	15	14
Dog bite	1064	1216	1073
Dysentery, bacillary	7	10	2
German measles	102	1191	523
Gonorrhea	332	453	368

Typhoid fever	3	2	2
Undulant fever	5	9	4
Whooping cough	499	476	604

*Three-year median

†Five-year median

COMMENT

The upward trend in the number of cases of diphtheria since July of last year has finally halted. The number of cases reported in April is approximately half the record for March, however, the number of cases is still approximately three times as great as in April, 1946 and three times the seven-year median. This drop was partly due to the usual seasonal decline, but undoubtedly the active immunization programs that have been conducted throughout the Commonwealth during the past few months are having an effect.

The drop in the number of cases of measles and German measles noted last month was more marked in April, both diseases being much below the seven-year median for the month.

Scarlet fever showed a marked drop, there being half the number of cases reported for April, 1946, and one third the seven-year median.

Diseases above the seven-year median for the month are chicken pox, bacillary dysentery, typhoid fever and undulant fever.

Below the seven-year median are dog bite, mumps, lobar pneumonia, poliomyelitis and whooping cough.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Actinomycosis was reported from Springfield, 1, total, 1. Diphtheria was reported from Arlington, 1, Boston, 17, Brookline, 1, Cambridge, 9, Canton, 1, Chelsea, 1, Everett, 1, Framingham, 1, Hinsdale, 1, Lowell, 2, Lynn, 2, Malden, 2, Medford, 2, Rockland, 1, Saugus, 1, Stoneham, 1, Wakefield, 1, Worcester, 1, total, 46.

Dysentery, amebic, was reported from Fitchburg, 1, New Bedford, 1, total, 2.

Dysentery, bacillary, was reported from Boston, 1, Melrose, 1, Worcester, 5, total, 7.

Malaria was reported from Boston, 1, Medford, 1, Raynham, 1, total, 3.

Meningitis, meningococcal, was reported from Boston, 3, Cambridge, 1, Fall River, 1, Holbrook, 1, Lenox, 1, Somerville, 1, Wakefield, 1, total, 9.

Meningitis, Pfeiffer-bacillus, was reported from Framingham, 1, Lynnfield, 1, Seekonk, 1, Worcester, 2, total, 5.

Meningitis, pneumococcal, was reported from Ashland, 1, Haverhill, 1, Springfield, 1, total, 3.

Meningitis, other forms, was reported from Boston, 1, total, 1.

Meningitis, undetermined, was reported from Cambridge, 2, total, 2.

Salmonellosis was reported from Boston, 3, Chicopee, 1, Holyoke, 1, Ludlow, 1, Lynn, 1, Palmer, 1, Salem, 1, West Bridgewater, 3, Worcester, 4, total, 16.

Septic sore throat was reported from Amesbury, Boston, 10, Everett, 1, Grafton, 2, Haverhill, 1, Medford, Merrimac, 2, total, 18.

Trichinosis was reported from Attleboro, 2, Boston, total, 6.

Typhoid fever was reported from Beverly, 1, Boston, Watertown, 1, total, 3.

Undulant fever was reported from Auburn, 1, Lancaster, Worcester, 3, total, 5.

BOOK REVIEWS

Neurosis and the Mental Health Services By C P Blacke, M.A., M.D., F.R.C.P. With a foreword by Sir Wilko Jameson, K.C.B., M.A., M.D., LL.D., F.R.C.P. 8°, cloth 218 pp., with 56 tables. New York: Oxford University Press, 1946. \$5.00.

This book is a review of present-day thinking and planning for psychiatry in England. It is a report of a serious and systematic survey of current problems and trends worked out in the careful and methodical way for which civil commissions in the British Isles are famous. It contains a great mass of detailed information and much discussion of nearly every phase of mental health so far as it is the responsibility of mental health services and also certain essential points and conclusions that are worth noting.

In the first place, between 1938 and 1942, there was an increase in the numbers and proportions of neurotic patients seen at two hundred and sixteen psychiatric clinics in England and Wales. The investigators who undertook this study came to the conclusion that this phenomenon did not represent a real increase of neurosis attributable to the war but rather a growing use of the country's psychiatric services by general practitioners, they believed that it might have occurred in the absence of war. Secondly, cases of neurosis attributed by psychiatrists to the effects of air raids were astonishingly few. And, finally, one of the most significant facts revealed is the marked disparity in the psychiatric services available in different parts of the country. The best facilities were found in London and the poorest in Wales.

The original purpose of this survey was to throw light on how the outpatient psychiatric services had been affected by the war. It was carried out by thirty-three investigators, who carefully combed the eleven civil defense regions of England and Wales for facts. In doing this they concerned themselves primarily with outpatient services. Psychiatric wards and child-guidance services were not included. Thus, the report deals with ambulatory cases of psychoneurosis for the most part, and relatively little emphasis is given cases requiring inpatient facilities and institutional care, which are dealt with regularly in the annual reports of the mental hospitals, whereas this report is the first of its kind published since the war and one of the few ever published.

The book is a valuable source of well documented facts and unique as an up-to-date volume for reference.

Modern Development of Chemotherapy By E. Havinga, H. W. Julius, H. Veldstra and K. C. Winkler. 8°, paper, 175 pp., with 31 illustrations and 8 tables. New York: Elsevier Publishing Company, Incorporated, 1946. \$3.50.

Research in Holland continued intensively in all directions during World War II, and this monograph reviews the work done in the field of chemotherapy during the war period ending on V E Day. The review is necessarily confined to material published in Dutch periodicals, since reports from other countries were not available. The work is confined to the sulfonamides and is divided into the following sections: mechanism of the action of the sulfonamides and of para-aminobenzoic acid, chemical investigations devoted to the synthesis and activity of sulfanilamide derivatives and related compounds, and pharmacologic, immunologic and clinical investigations. The last chapter, by J. J. Duyvené de Wit, discusses a new drug "Expansine." In the section on chemistry is given a tabular list of seventy-three synthetic compounds with their chemical structure and activity. To each special section is appended a list of references of the work of Dutch authors published at home and abroad. The material is well organized and well published in every way. The

Pharmacology and Therapeutics Originally written by Arthur Cushman, M.A., M.D., LL.D., F.R.S. By Arthur Grollman, Ph.D., M.D., professor of medicine and chairman, Department of Experimental Medicine, and professor of pharmacology and chairman, Department of Physiology and Pharmacology, Southwestern Medical College, attending physician, Parkland Hospital, and consultant in internal medicine, Baylor University Hospital, and Donald Slaughter, M.D., dean of University of South Dakota School of Medical Sciences. Thirteenth edition, thoroughly revised 8° cloth, 744 pp., with 74 illustrations Philadelphia Lea and Febiger, 1947 \$3.50

This standard reference book, first published in 1899, has been thoroughly revised and brought up to date by the new material in the fields of chemotherapy, endocrinology and the vitamins has been incorporated, and some of the older out-of-date material has been deleted. The present edition is in accord with the *USP XII* and the *Pharmacopoeia*, 1932. A list of selected references is appended to each chapter. A comprehensive index concludes the volume. The book is well published and is recommended for all medical libraries and allied libraries, it should be useful as a reference book for the physician and the medical student.

Endocrinology By Robert B. Greenblatt, M.D., C.M., professor of endocrinology, University of Georgia School of Medicine and director, Sex Endocrine Clinic, University Hospital, Augusta, Georgia. With a foreword by G. Lomax Kelly, M.D., dean, University of Georgia School of Medicine. Third edition 8°, cloth, 302 pp., with 58 figures, color plates and 20 tables and charts. Springfield, Illinois Charles C. Thomas, 1947 \$4.75

This edition of a standard book has been enlarged and brought up to date. It is intended for the busy, general practitioner and is written accordingly with emphasis on treatment. The material is well organized and considered under female and male endocrinology and hormonology. The chapters are short and concise, and a short list of pertinent references is appended to each. The volume is well published in the usual Thomas style. The various separate sets of numbers of figures and tables for each chapter are confusing and not good for reference purposes. (Consecutive numbering throughout the volume is more satisfactory for general use.) The usefulness of the work is attested by its popularity, requiring three editions and one extra printing since its first publication in 1941.

The Story of Human Birth By Alan Frank Guttmacher, M.D., associate professor of obstetrics, Johns Hopkins University School of Medicine, visiting obstetrician, Johns Hopkins Hospital, and chief in obstetrics, Sinai Hospital, Baltimore. Paper, 214 pp., with 7 illustrations. New York: Pennington Books, Incorporated, 1947 25 cents

Originally published in 1937 by the Viking Press under the title *Into This Universe*, the text has been cut and condensed from the original but has been revised and brought up to date for this popular pocket edition. The presentation is revised, the material well organized, and the text written in plain language for the laity. Appended to the text is a list of books for recommended reading. This list may have been suitable for the original edition of 1937 but seems out of place in this inexpensive issue. It is incongruous to suggest the reading of Paré, Mauriceau, Guillemeau, Roesslin and Raynalde in the early rare English editions, obtainable in large medical libraries. Also, the technical references to the placenta, the embryo, various aspects of labor and the puerperium, even in the German language, are out of place in this type of book.

In late years there has been a decided improvement in the standard of medical books written for the general public and more physicians of high professional standing are writing such books, providing a decided contrast to the low standard of popular output of the past decade.

Physiological Chemistry By Philip B. Hawk, Ph.D., Food Research Laboratories, Incorporated, and L. Oser, Ph.D., director, Food Research Laboratories

Incorporated, and William H. Summerson, Ph.D., associate professor of biochemistry, Cornell University Medical College. Twelfth edition 8°, cloth, 1323 pp., with 329 illustrations. Philadelphia: Blakiston Company, 1947 \$10.00

This standard textbook which was first published in 1907 has enjoyed a continuous existence of forty years, and for this twelfth edition the subject matter has been completely brought up to date in the light of present-day knowledge. Many chapters have been entirely rewritten, and much new material added, including sections on the polarograph, isotopes, sulfonamides, metabolic antagonists and antibiotics, vitamins, Warburg tissue-slice procedure, photometric analysis, electrophoretic fractionation of plasma proteins and composition of foods. Many new quantitative procedures for blood and urine analysis have been added. Obsolete and minor material has been deleted. The text is well arranged and well documented with tables and formulas. A short pertinent bibliography is appended to each chapter. A comprehensive index concludes the volume. The book is well published in every way and the publishers are to be congratulated on the use of a light-weight but substantial paper for such a large volume. The book is recommended for all medical libraries and for the libraries of all physicians and others interested in the subject.

The Lung By William Snow Miller, M.D., Sc.D. Second edition 8°, cloth, 222 pp., with 168 illustrations. Springfield, Illinois: Charles C. Thomas, 1947 \$7.50

In this second edition of his authoritative monograph on the structure of the lung Dr. Miller has not made any fundamental changes in the text. Some additional illustrations have been added. The results of Professor O. Larzell's studies on the nerves of the visceral pleura have been incorporated in the chapter on the pleura. During the period between the publication of the first edition in 1937 and the present edition the author has not found any reason for changing his opinion that there is an epithelium lining the alveoli of the lung and that it is continuous although some investigators think differently. A long bibliography is appended to the text. The type, printing and illustrations leave nothing to be desired. The publisher has surpassed his usual high standard of publication. The monograph is recommended for all medical libraries and to all physicians and others interested in the lungs.

Gynecological and Obstetrical Pathology With clinical and endocrine relations By Emil Novak, M.D., Sc.D. (Hon., Dublin), associate in gynecology, Johns Hopkins University School of Medicine, and gynecologist, Bon Secours and St. Agnes hospitals, Baltimore. Second edition 8°, cloth, 570 pp., with 545 illustrations, 15 in color. Philadelphia: W. B. Saunders Company, 1947 \$7.50

This standard work has been revised to include advances since the publication of the first edition in 1938. Over a hundred new illustrations have been added, and the selective bibliographies have been brought up to date. The volume is well published in every way. The art work is excellent. This authoritative text is recommended for all medical libraries.

Science Digest Reader A selection of outstanding articles published in *Science Digest* during the past ten years 8°, cloth, 310 pp. Chicago: Windsor Press, 1947 \$3.00

This collection of articles originally condensed and published in *Science Digest* contains many of medical interest, including those on health, personal and mental hygiene, common diseases, diet, drugs and anesthesia. The general scientific articles on atomic energy, rockets and jet planes, radar, the weather and other topics are informative and interesting. The book is well published and should prove useful as light reading in any medical-history collection.

A Surgeon's Domain By Bertram M. Bernheim, M.D., associate professor of surgery, Johns Hopkins University School of Medicine, and visiting surgeon, Johns Hopkins

with a good large type on soft paper. The whole series of volumes, 1943-1946, is recommended for medical and public libraries and should prove of value to all persons interested in public health.

Hospital Care of the Surgical Patient. A surgeon's handbook With an appendix, "The Treatment of Wounds." By George Crile, Jr., M.D., surgeon, Cleveland Clinic, and Franklin L. Snively, Jr., M.D., assistant surgeon, Cleveland Clinic. With a foreword by Evarts A. Graham, M.D., Bixby Professor of Surgery, Washington University School of Medicine, Saint Louis. Second edition. 8°, cloth, 288 pp., with 25 illustrations. Springfield, Illinois: Charles C. Thomas, 1946. \$3.50.

This manual, which is written primarily for the young surgeon about to begin graduate study of surgery, combines in a small volume the clinical, physiologic and technical principles important in the care of the surgical patient. The work is divided into the following sections: physiologic principles, surgical complications, preparation of the patient for operation, postoperative care, technic of hospital procedures and treatment of wounds. There is an important chapter on the relations of the house officer to the patient and his relatives, and to the hospital and department personnel. This manual should prove useful to the young surgeon.

Textbook of Medical Treatment. By various authors. Edited by D. M. Dunlop, B.A. (Oxon), F.R.C.P. (Edin.), M.R.C.P. (Lond.), professor of therapeutics and clinical medicine, University of Edinburgh, and physician, Royal Infirmary, Edinburgh, and L. S. P. Davison, B.A. (Camb.), M.D., F.R.C.P. (Edin.), F.R.C.P. (Lond.), and J. W. McNee, D.S.O., D.Sc., M.D. (Glas.), F.R.C.P. (Edin.), F.R.C.P. (Lond.). Fourth edition. 8°, cloth, 923 pp. Baltimore: Williams and Wilkins Company, 1946. \$5.00.

This popular treatise written by a number of English authorities, first published in 1939, has been completely revised and brought up to date. The format has been changed by enlargement in the size of the page, resulting in a reduction in the number of pages by about 25 per cent although the amount of text has been slightly increased. A new chapter on penicillin has been added. The sections on venereal diseases and diseases of the thyroid gland have been almost entirely rewritten, and the chapter on diseases of the respiratory system has been extensively revised. A postscript contains a short account of DDT as a means of preventing tropical diseases. A valuable appendix comprises a table of official preparations with their proprietary names. Emphasis has been placed on general management in therapy rather than on a mere enumeration of drugs and other therapeutic agents. A comprehensive index concludes the volume, which is well published in every way. The material is of necessity condensed, but the book should prove valuable as a reference work because of the view it gives of British therapeutics.

Le malattie del sangue manuale per medici e studenti. By Adolfo Ferrata, Clinico Medico della Università di Pavia. 8°, cloth, 751 pp., with 289 illustrations, of which 112 are colored, and 6 colored plates. Milano: Società Editrice Libreria, 1946.

This special treatise is based on an experience of over forty years in the study of hematology by the late Professor Ferrata. The whole subject is covered including the blood and blood-forming organs. The material is well organized, and a simple classification is used. The first chapter is on the morphology, genesis and physiology of the blood, including sections on blood-grouping and the velocity of sedimentation of erythrocytes. This is followed by chapters on the anemias, leukemias, hemorrhagic diatheses, malignant granuloma, mononucleosis, reticulosis, polyglobulism and polycythemia, diseases of the spleen and cytologic alterations of the blood in infectious diseases, with a chapter on the technic of blood research. A good index concludes the volume. The text is well printed with a good type. The color illustrations are excellent. This book reflects the best Italian practice and should be in all large medical libraries and in special collections on the blood.

Hygiene. A textbook for college students on physical and mental health from personal and public aspects. By Florence Meredith, M.D. Fourth edition. 8°, cloth, 838 pp., with 155 illustrations. Philadelphia: Blakiston Company, 1946. \$4.00.

This standard textbook, first published in 1926 and revised in 1941, has been entirely reset and revised to include the advances in knowledge of the past five years. The material has been rearranged with the objective of dividing the subject into its logical major divisions. It is expected that this new arrangement will afford the student the opportunity of seeing the whole field of health as a unit and of evaluating its various separate fields. The material is well arranged and the text is well printed with a good type on good paper. The illustrations are adequate for their purpose. The book is recommended for all educational and public libraries and should be useful as a ready reference source in medical libraries.

Digitalis and Other Cardiotonic Drugs. By Eli Rodin Movit, M.D., internist, Veterans Administration Facility, San Francisco. 8°, cloth, 204 pp., with 12 figures and 9 tables. New York: Oxford University Press, 1946. \$5.75.

In this monograph the author has brought together all the available literature on digitalis and its glycoside derivatives, as well as on strophanthus, squill and cardiotonic agents of plant and animal origin. The two botanical species of digitalis—*folium* and *lanata*—are discussed at length in their physiologic, pharmacologic, toxic and clinical aspects. Digilamid, lanatoside C and digoxin, derivatives of the *lanata* species, are considered at length. A special chapter is devoted to strophanthin, the active principle of strophanthus, another to squill and its derivatives. Thevetin and bufotalin, a toad poison, as well as other glycosides of plant origin, are briefly considered. The author discusses the relative merits of the various substances and their clinical indications. A bibliography is appended to each chapter. The text is well printed with a good type on good paper. The monograph is recommended for all medical libraries and should be of value to physicians interested in heart disease.

The New Science of Surgery. By Frank G. Slaughter, M.D. 8°, cloth, 286 pp. New York: Julian Messner, 1946. \$4.00.

Dr. Slaughter has written an interesting narrative for the layman on the recent advances in surgery. He discusses shock, anesthesia, penicillin and the sulfonamides, operation on the chest, pancreas, brain and heart, vascular surgery, treatment by cold, burns, plastic surgery of the face, psychosomatic surgery and cancer. This volume is recommended for public libraries and as light reading for medical students.

Modern Dermatology and Syphilology. By S. William Becker, M.D., clinical professor of dermatology, University of Chicago School of Medicine, and Maximilian E. Obermayer, M.D., clinical professor and chairman, Department of Dermatology, University of Southern California School of Medicine. Second edition. 4°, cloth, 1017 pp., with 461 illustrations and 37 color plates. Philadelphia: J. B. Lippincott Company, 1947. \$18.00.

This treatise has been revised and brought up to date. The use of Dioxan, penicillin and the sulfonamides is discussed. The chapters on therapy and pigmentary dermatoses have been enlarged. The chapter on trophic and deficiency diseases has been completely rewritten to reflect the advances in vitamin therapy. There are new chapters on leprosy and tropical diseases. In the newly revised section on syphilis the value of quantitative serologic and verification tests for diagnosis, rapid treatment methods and the use of penicillin are discussed. A classification chart has been appended to the chapter on cutaneous diseases due to animal organisms. The text is well printed with a good type in a two-column format, but the weight is much too heavy for the volume to be easily handled. All color plates are tipped in and a lighter paper could have been used to advantage. The book is recommended for all medical libraries.

PREGNANCY FOLLOWING LUMBODORSAL SPLANCHNICECTOMY FOR ESSENTIAL AND MALIGNANT HYPERTENSION AND HYPERTENSION ASSOCIATED WITH CHRONIC PYELONEPHRITIS

JOHN L. NEWELL, M.D.,* AND REGINALD H. SMITHWICK, M.D.†

BOSTON

THE prognosis in pregnancy complicated by a pre-existing hypertension with or without renal disease is notoriously poor for both the mother and the infant. Corwin and Herrick,^{1 2} in their classic papers written in 1927, made the following statement:

Very few women who begin pregnancy with a blood pressure above 150 systolic or 100 diastolic can go through pregnancy successfully, that is with a living child. It is our opinion moreover, that pregnancy does much to accelerate the progress of chronic cardiovascular disease, that it may bring it out when latent and is to be avoided when the disorder has made evident inroads.

Severe hypertension of any origin is considered by many others to be a strong indication for therapeutic abortion. Watson³ regarded a pronounced hypertension with or without albuminuria as an indication for the induction of abortion. Fishberg⁴ observed that the pregnancy should be terminated if the blood pressure continued to rise or evidence of cardiac or renal insufficiency appeared.

In the 14 cases reported below all the patients had arterial hypertension, the blood pressures averaging 196 systolic, 130 diastolic, on admission prior to splanchnicectomy. For the most part the prenatal care and deliveries were conducted by obstetricians in the localities in which the patients resided. The blood-pressure reactions were studied by the postural and cold test in the first trimester and in most cases at seven months of pregnancy and at six weeks post partum.

As might have been expected with this type of case, the average age at delivery was thirty-one years. The average parity was 2.3. The time elapsing between the diagnosis of hypertension and the splanchnicectomy averaged seventy-five months, and the time between splanchnicectomy and the pregnancy studied averaged thirty-one months,

with the exception of a case in which splanchnicectomy was performed during the first trimester. The blood pressure following splanchnicectomy prior to the pregnancies averaged 135 systolic, 87 diastolic, and only 2 patients had persistent albuminuria.

The nature of the hypertension is of interest. Seven patients were classified preoperatively as having so-called "essential hypertension." Three gravida I's and 2 gravida II's, all without demonstrable kidney disease, were known to have had hypertension prior to their pregnancies. One gravida III and 1 gravida V, also without demonstrable kidney disease, developed hypertension during the second and first pregnancies respectively. Two gravida I's and 2 gravida II's were classified as having essential hypertension and associated chronic pyelonephritis, the presence of the latter being proved by renal studies, by gross inspection of the kidneys at operation and by biopsies taken from the kidneys. Two gravida II's developed both hypertension and pyelonephritis during the first pregnancies. The 2 remaining patients in this group developed renal disease and hypertension prior to their pregnancies. There were 3 cases of malignant hypertension, with pyelonephritis in 2. In a gravida II the disease began two years after the first pregnancy, another gravida II had had eclampsia during her first pregnancy six years earlier and known hypertension for two years, and in a gravida V the disease had become manifest during her third pregnancy. Thus, in all cases, hypertension antedated the pregnancies under discussion, and in 3 cases previous pregnancies had been interrupted because of hypertension.

In 9 cases the blood pressure during pregnancy remained within normal limits, and there was no albuminuria. The other 5 patients showed no significant elevation of blood pressure until the third trimester, when 2 developed marked elevation (above 180 systolic). In one of these cases a

*Assistant in obstetrics, Harvard Medical School; assistant obstetrician, 2nd Lt. in Hospital; associate obstetrician, Massachusetts General Hospital.

†Professor of surgery, Boston University School of Medicine; surgeon-in-chief, Massachusetts Memorial Hospitals; member, Board of Consultants, Massachusetts General Hospital.

Hospital and Union Memorial Hospital 8th, cloth, 253 pp
New York W W Norton and Company, Incorporated,
1947 \$3 00

In this popular book, Dr Bernheim, noted for his work on transfusion and the vascular system, writes about surgery and surgeons on the basis of his own life and experiences. The story is written in a charming narrative style covering various aspects of the practice of surgery and high lighting the daily life, trials and tribulations of the surgeon. This narrative should find a place in the libraries of surgeons and in collections of light reading for medical students and in medical-history collections.

Principles and Practice of Obstetrics By Joseph B De Lee, M.D., and J P Greenhill, M.D., attending obstetrician and gynecologist, Michael Reese Hospital, obstetrician and gynecologist, associate staff, Chicago Lying-In Hospital, chairman, Department of Gynecology, Cook County Hospital, and professor of gynecology, Cook County School of Medicine. Ninth edition 4th, cloth, 1011 pp, with 1108 illustrations, 211 in color Philadelphia W B Saunders Company, 1947 \$10 00

This authoritative treatise, first published in 1913 by the late Dr De Lee, has been thoroughly revised and practically rewritten by Dr Greenhill. New chapters have been added on minor disturbances of pregnancy, premature labor, prolonged pregnancy or post-maturity and missed labor, fetal erythroblastosis, care of premature babies, circumcision and pemphigus neonatorum. The chapters on physiology of the fetus and ante-partum and post-partum care have been replaced by new ones. Additional material has been added to the subject of analgesia and anesthesia, including detailed information on direct, local and infiltration anesthesia, and caudal anesthesia. New material has been added to the sections on diseases of the blood and on surgical operations. New material has also been incorporated in the chapters on hyperemesis gravidarum, toxemias of pregnancy, post-partum hemorrhage, placenta previa, abruptio placentae, placenta accreta and acute and chronic infectious diseases complicating pregnancy. Detailed information is given on the use of penicillin and the sulfonamides, and the importance of German measles in obstetrics is emphasized.

Many new illustrations have been added, and a bibliography covering all references in the text is appended to each chapter. The illustrations are excellent, the text is well printed with a good type on good paper. A good index concludes the volume. This book is recommended for all medical libraries and the libraries of physicians practicing obstetrics.

NOTICES

JOSEPH H PRATT DIAGNOSTIC HOSPITAL

30 Bennet Street, Boston
Lecture Hall, 9-10 a m

MEDICAL CONFERENCE PROGRAM

- Wednesday, June 4 — Chemotherapy of Hodgkin's Disease and Leukemia Dr Louis Weisfuse
Friday, June 6 — Intracranial Aneurysms Dr William Sweet
Wednesday, June 11 — Treatment of Hyperthyroidism Dr Willard Vander Laan
Friday, June 13 — A Summary of Congenital Heart Disease Dr Sidney Farber
Wednesday, June 18 — Pediatric Clinicopathological Conference Drs James M Baty and H E MacMahon
Friday, June 20 — Hormonal Alteration of Advanced Carcinoma of the Breast Dr Ira Nathanson
Wednesday, June 25 — Reginald Heber Fitz's Contribution to Acute Appendicitis and Acute Pancreatitis Dr Hyman Morrison
Friday, June 27 — Ideology and Management of Hemoglobinuric Nephrosis Dr C H Burnett

On Tuesday and Thursday mornings, Dr S J Thannhauser will give medical clinics on hospital cases. On Saturday mornings, clinics will be given by Dr William Dameshek. Medical rounds are conducted each weekday by members of the staff from 12 00 to 1 00 in the lecture hall.

All exercises are open to the medical profession.

NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the of the New England Hospital for Women and Children be held on Thursday, June 5, at 7 15 p m, in the class of the Nurses' Residence. Dr Allan M Butler will discuss the subject "Parenteral Fluid Therapy with Potassium Solution." Dr Eleanore C Zaudy will be chairman.

NORTON MEDICAL AWARD

W W Norton and Company is again offering the Norton Medical Award for book manuscripts written for the public by professional workers in the field of medicine. Terms of the award have been slightly altered. The publishers now set no final closing date for the submission of manuscripts, which may be submitted at any time, the award not being limited to any one year. The Norton Medical Award offers \$5000 as a guaranteed advance against royalty. Either complete manuscripts or a detailed table of contents together with one hundred pages of manuscript may be submitted. A descriptive folder giving full details of the terms of the award may be secured on request from the publisher W W Norton and Company, Incorporated, 101 Fifth Avenue New York 3, N Y.

Books that have previously won the Norton Medical Award are *The Doctor's Job*, by Carl Binger, M.D., *Doctors in Doctors' West*, by Edward H Hume, M.D., and *A Surge Domain*, by Bertram M Bernheim, M.D.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, JUNE 5

THURSDAY JUNE 5

7 15 p m Clinical Conference and Staff Meeting Nurses' Residence, New England Hospital for Women and Children

FRIDAY JUNE 6

*9 00-10 00 a m Intracranial Aneurysms Dr William Sweet
Joseph H Pratt Diagnostic Hospital

*10 00 a m-12 00 m Medical Staff Rounds Peter Bent Brigham Hospital

MONDAY JUNE 9

*12 15-1 15 p m Clinicopathological Conference Peter Bent Brigham Hospital

TUESDAY JUNE 10

*12 15-1 15 p m Clinicoradiological Conference Peter Bent Brigham Hospital

WEDNESDAY JUNE 11

*9 00-10 00 a m Treatment of Hyperthyroidism Dr Willard Vander Laan Joseph H Pratt Diagnostic Hospital

*11 00 a m-12 00 m Medical Clinic Amphitheater Children's Hospital

*12 00 m Clinicopathological Conference (Children's Hospital) Amphitheater Peter Bent Brigham Hospital

*2 00-3 00 p m Combined Clinic by the Medical Surgical and Orthopedic Services Amphitheater Children's Hospital

*Open to the medical profession

CASE 2. This patient was 20 years of age at the time of her final admission in November, 1940. At the age of 4 she had been admitted for a urinary-tract infection and had subsequently been followed in the Out Patient Department. During the 3 years prior to splanchnicectomy she had been admitted to the hospital twice because of urinary-tract infections caused by an organism of the colon-bacillus group. This infection responded to chemotherapy, and the urine became intermittently sterile. The blood pressure had always been elevated, and during this period the hypertension became progressively severer and the eye-ground changes progressively more marked. The family history was noncontributory.

On final admission the blood pressure was 205/140, and the range during postural and cold tests was from 205/150 to 174/110. The eye grounds showed Grade II changes, both spastic and sclerotic. The heart was normal in size and slightly altered in shape. The nonprotein nitrogen was 26 mg per 100 cc, a phenolsulfonephthalein test showed 15 per cent excretion of the dye in 15 minutes and 50 per cent in 2 hours. The maximum urinary concentration was 1012. There was a +++ test for albumin, and the sediment contained a few to many white cells. Cultures of the urine showed abundant growth of nonhemolytic streptococci. Intravenous pyelograms were not remarkable. On sedation the blood pressure fell to 145/100.

On November 20 the first stage of a lumbodorsal splanchnicectomy was performed, the sympathetic trunk on the left being removed from the tenth dorsal to the second lumbar segment inclusive. The second stage was performed on December 3, the sympathetic trunk being removed from the tenth dorsal to the first lumbar inclusive. The great splanchnic nerves were removed on both sides from the celiac ganglia to the midthoracic level. At operation both kidneys were found to be irregularly scarred, contracted and lobulated, a finding typical of chronic pyelonephritis. Biopsies taken from both kidneys showed typical chronic pyelonephritis and chronic vascular nephritis, Grade III. The patient was discharged on December 16, the blood pressure being 133/104. Two years after the splanchnicectomy the blood pressure was 109/82.

The patient became pregnant for the first time 3½ years after operation, the blood pressure being 128/94 and the urine containing no albumin. During the 6th month of pregnancy the blood pressure was 122/88, but at 34 weeks a blood pressure of 170/110 developed and the urine showed a +++ test for albumin. She was delivered by cesarean section of an infant weighing 3 pounds, 9 ounces, who survived. Two months post partum and 51 months after operation the blood pressure was 138/94.

CASE 3. A 28-year-old gravida I was admitted in May, 1942, for hypertension. For 15 years she had had headaches associated with vomiting. Nine years previously she was found to have a slightly elevated blood pressure, and 18 months prior to admission the blood pressure was 180/120. Both parents, who were 49 and 56 years of age, had hypertension.

The blood pressure on admission was 180/130, the range during postural and cold tests being 198/140 to 148/88. The retinal vessels showed spasm. The heart was normal in size and shape. An electrocardiogram was within normal limits. The nonprotein nitrogen was 26 mg per 100 cc. A phenolsulfonephthalein test showed 32 per cent excretion of the dye in 30 minutes and 65 per cent in 2 hours. The urine, which concentrated to 1026, gave a + test for albumin, and the sediment contained 10 white cells per high-power field. On June 1 the first stage of a lumbodorsal splanchnicectomy was performed, with removal of the sympathetic trunk from the ninth dorsal to the third lumbar segment, inclusive, on the right. Two weeks later, at a similar operation, the sympathetic trunk on the left side was removed from the ninth dorsal to the second lumbar inclusive. The great splanchnic nerves were removed on both sides from the celiac ganglia to the midthoracic level. Biopsies of the kidney were reported as showing a chronic vascular nephritis, Grade II. After an uneventful convalescence the patient was discharged with a blood pressure of 140/100.

In August, 1943, she became pregnant. The pregnancy was uneventful, the blood pressure varying between 120/84 and 185/120 and the urine remaining free of albumin. At the 30th week of pregnancy she was checked at the hypertension

clinic and found to have a blood pressure of 138/90. Three hours later she experienced massive vaginal bleeding.

On admission to the hospital the blood pressure was 180/120, and the urine gave a +++ test for albumin. The uterus was firm and did not relax. A diagnosis of premature separation of the placenta was made. Since the fetal heart beat disappeared 20 minutes after admission, the membranes were ruptured and labor was stimulated with minimal doses of Pitocin. Ten hours later a stillborn, premature infant was delivered by low forceps. The placenta was completely separated, and the uterus was filled with large blood clots. The patient suffered moderate shock and required two transfusions during labor. She was discharged on the 13th postpartum day, when the blood pressure was 148/98.

The patient experienced a second pregnancy, which terminated successfully in March, 1945, with a normal delivery of a living infant weighing 4 pounds, 4 ounces. This delivery was also complicated by premature separation of the placenta. During pregnancy the blood pressure averaged 155/105, and the urine remained free of albumin. Labor was painless until the head distended the perineum.

CASE 4. A 28-year-old gravida I had first been known to have hypertension when she was 15 years old. The blood pressure at times was recorded as over 200 systolic. The admission blood pressure was 205/150, the range during postural and cold tests being 205/154 to 148/110. The eye grounds were classified as Grade I. A 7-foot plate showed the heart to be normal in size and shape. The electrocardiogram was normal. The nonprotein nitrogen was 28 mg per 100 cc. A phenolsulfonephthalein test showed 30 per cent excretion of the dye in 15 minutes and 93 per cent excretion in 2 hours. The urine, which concentrated to 1022, gave a + test for albumin, the sediment was normal, as was an intravenous pyelogram. On sedation the blood pressure fell to 138/110.

In February, 1944, the first stage of a bilateral lumbodorsal splanchnicectomy was performed, the left sympathetic trunk being removed from the eighth dorsal to the first lumbar segment, inclusive. Two weeks later the second stage was performed, the right sympathetic trunk being removed from the seventh dorsal to the second lumbar inclusive. The great splanchnic nerves were removed on both sides from the celiac ganglia to the midthoracic level. A renal biopsy showed a chronic vascular nephritis, Grade III.

Three months later, when the patient became pregnant, the blood pressure was 140/100, and the urine was normal. At 7 months the sediment contained white cells in clumps. This cleared with sulfadiazine therapy. At 34 weeks the blood pressure was 160/104, and 2 weeks later it rose to 190/128. The patient remained at bed rest in the hospital until the 40th week of pregnancy, when she started in labor spontaneously and was delivered normally of a living infant. For the 4 weeks prior to delivery while at bed rest she had had no complaints, and the urine had remained free of albumin. The blood pressure varied widely, averaging 170/120. On several occasions it reached 180/130, but a few hours later was found to be 126/90. Following delivery the blood pressure continued to be labile and was 170/110 when the patient was discharged. Eight months post partum the reading was 106/96 with the patient in the horizontal position. It could be raised to 160/118 when she was standing and stimulated by cold.

CASE 5. A 28-year-old gravida II was admitted in May, 1942, with a diagnosis of malignant hypertension. Ten years previously she had experienced a normal pregnancy. Three years later she began having headaches, which became progressively severer.

The blood pressure on admission was 245/140, the range during postural and cold tests being 250/170 to 196/132. The eye grounds showed hypertensive retinopathy with papilledema. A 7-foot heart plate showed definite enlargement. The heart was altered in shape, and the aorta was tortuous. An electrocardiogram was consistent with hypertensive heart disease. The nonprotein nitrogen was 33 mg per 100 cc. A phenolsulfonephthalein test showed 15 per cent excretion of the dye in 15 minutes and 15 per cent in 2 hours. The urine showed a specific gravity of 1012, with a ++ test for albumin, and the sediment contained rare red cells. Intravenous pyelograms were normal. On sedation the blood pressure fell to 150/110.

++++ test for albumin necessitated interruption of the pregnancy at the thirty-fourth week. Three cases showed only moderate hypertension (blood pressures below 160 systolic, 90 diastolic), but 1 of these patients, who had developed a premature separation of the placenta in her first pregnancy, successfully completed her second pregnancy after the termination of the study. In this group there were normal deliveries in 11 cases and cesarean sections in 3, the indication being a previous hys-

terectomy. The conservative and wisest procedure was to terminate the pregnancy. In view of our previous experience with pregnancy following splanchnicectomy, however, the consultant agreed to postpone abortion until the results of the splanchnicectomy could be determined, since in our opinion this latter procedure was indicated regardless of the pregnancy.* The family history revealed that the patient's mother had died of kidney disease.

The blood pressure on admission was 180/120, and the range during postural and cold tests was 138/106 to 204/144. The eye grounds were normal. A 7-foot heart plate was consistent with hypertension. An electrocardiogram and the nonprotein nitrogen were normal. A phenolsulfonephthalein

FIGURE 1 Case 1

This chart shows the blood-pressure levels before lumbodorsal splanchnicectomy and ten months later, one month after delivery. The postural and "cold" blood-pressure readings are compared. In recording these, readings are taken every minute for five minutes with the patient lying, sitting and standing. A cold test is then performed with the patient lying and is repeated with the patient standing. The postoperative (post-partum) range is shaded. This patient was six weeks pregnant when the splanchnicectomy was performed.

terotomy in 2 cases and fulminating pre-eclampsia in another. Thirteen babies are living and well—2 were delivered prematurely. One infant was still-born owing to premature separation of the placenta. The puerperium was uncomplicated in all cases except for the patient in Case 11, who developed a post-partum psychosis. The average blood pressure was 134 systolic, 89 diastolic, at two weeks post partum and 133 systolic, 87 diastolic, at six or more weeks post partum. None of the patients had albuminuria at that time.

The following are brief abstracts of the case reports.

CASE 1. A 24-year-old gravida II had first been seen in the 9th month of her first pregnancy with a blood pressure of 168/110 but no albuminuria. The blood pressure remained in this range for the remainder of this pregnancy, and the patient was delivered at term of a living infant. She was next seen 3 years later with a blood pressure of 186/120. The blood pressure continued to rise during the next 6 months, when she was admitted to the hospital. At that time the patient was 6 weeks pregnant. The consultant from the hypertensive clinic and the obstetric consultant believed that

test showed 45 per cent excretion of the dye in 15 minutes and 65 per cent in 2 hours. The urine concentrated to 1020 and contained no albumin, and the sediment was normal, as was an intravenous pyelogram. On sedation the blood pressure fell to 120/50. The Aschheim-Zondek test was positive.

On July 1, 1944, the first stage of a bilateral lumbodorsal splanchnicectomy was performed, with removal of the sympathetic trunk from the eighth dorsal to the third lumbar segment inclusive. Two weeks later a similar operation was performed on the left side, with removal of the sympathetic trunk from the eighth dorsal to the second lumbar segment inclusive. The great splanchnic nerves were removed on both sides from the celiac ganglions to the midthoracic level. Renal biopsies revealed chronic vascular nephritis, Grade II. The patient experienced an uneventful convalescence, and at discharge the blood pressure was 110/80.

During the remainder of this pregnancy the blood pressure was 110/70 to 104/90. There were no signs or symptoms of toxemia, and the urine was consistently free of albumin. On January 24, 1945, the patient was delivered of a living infant. The blood pressure during the puerperium varied between 102/60 and 130/100. At two subsequent post-partum visits the blood pressure was 128/78 and 132/80. Three months post partum the blood pressure was 120/80, and a month later it was 102/78. Blood-pressure data as revealed by the postural and cold tests are presented in Figure 1.

*In general we believe that the best results are obtained when the pregnancy follows the splanchnicectomy by at least twelve months. There may be a group of patients such as this one, however, in whom operation could be performed in the first trimester.

of blood pressure was detected. A year later the patient lost 25 pounds and suffered headaches that became worse during the 2 or 3 years preceding admission.

The blood pressure on admission was 225/130, the range during postural and cold tests being 226/146 to 184/114. The eye grounds were classified as Grade II. A 7-foot plate showed the heart to be normal in size and slightly altered in shape, the aorta being slightly tortuous. An electrocardiogram was normal. The nonprotein nitrogen was 26 mg per 100 cc and a phenolsulfonephthalein test showed 32 per cent excretion of the dye in 15 minutes and 55 per cent in 2 hours. The urine concentrated to 1019, gave a + test for albumin and contained a slightly abnormal sediment. Intravenous pyelograms were normal. On sedation the blood pressure fell to 122/80.

On November 22 the first stage of a lumbodorsal splanchnicectomy was performed. The sympathetic trunk was removed from the second dorsal to the first lumbar segment, inclusive. At a similar operation 2 weeks later the right trunk was removed from the ninth dorsal to the first lumbar. The great splanchnic nerves were removed from the celiac ganglions to the midthoracic level. The patient was discharged on December 13, the blood pressure ranging between 152/104 and 166/114.

She was readmitted for study in March, 1942, at which time she had no complaints. The blood pressure was 150/90 on admission but dropped to 110/94 with bed rest, the range being 150/90 to 80/40. The eye grounds were classified as Grade II. The cardiac status was considered normal. The renal blood flow (as measured by the Diodrast-clearance method) was 640 cc. per minute, or about two thirds normal.

The patient became pregnant in 1943. This pregnancy was uneventful throughout, with no signs or symptoms of toxemia and with delivery of a living infant at term. Two months post partum (62 months after operation) the patient was studied again. The blood pressure on admission was 122/82, and the range was from 164/114 to 128/88. An electrocardiogram and the kidney function tests were normal, and the eye grounds were completely normal.

CASE 8. A 31-year-old gravida III was first seen at the age of 29 years. She complained of severe headaches of 7 years' duration and had had known hypertension for 6 years. The family history was strongly positive for hypertensive disease. One year prior to admission she was delivered of a living child, the pregnancy being induced at 36 weeks because of a blood pressure of 230/120 and albuminuria. The puerperium was complicated by ptylitis. Four months before admission a therapeutic abortion had been performed.

On admission the blood pressure was 150/100, the range during postural and cold tests being 124/90 to 150/116. The heart was normal in size and shape, and the aorta was not tortuous. An electrocardiogram was normal, and the eye grounds were reported as showing Grade I changes. The specific gravity of the urine was 1.018, and there was no albumin; the sediment was normal. The nonprotein nitrogen was 20 mg per 100 cc. Intravenous pyelograms were normal except that there was slight evidence of pyelonephritis on the right side. On sedation the blood pressure fell to 110/78.

On March 19, 1943, the left sympathetic trunk was removed from the eighth dorsal to the second lumbar segment inclusive. On April 4 the right sympathetic trunk was removed from the ninth dorsal to the second lumbar inclusive. The great splanchnic nerves were removed on both sides from the celiac ganglions to the midthoracic level. Biopsies of the kidneys were reported as showing a Grade I chronic vascular nephrosis on the right and a Grade II chronic vascular nephrosis on the left.

The patient became pregnant 27 months after operation. At that time the blood pressure was 138/80, and the urine negative for albumin. The pregnancy was entirely normal throughout, the blood-pressure range being 120/78 to 140/90 and the urine consistently negative for albumin. An infant weighing 6 pounds, 3 ounces, was delivered normally in March 1946, after a short painless labor. Two weeks post partum the blood pressure was 120/80, and the urine normal.

CASE 9. A 32-year-old gravida III was admitted in March 1942, for hypertension. Nineteen months previously she had consulted a physician for prenatal care and had been found to have a systolic blood pressure of 200. Headache was the prominent symptom during this pregnancy, which terminated

normally, at term. Headache and tinnitus had subsequently persisted. The first pregnancy, 10 years previously, was believed to have been normal. The patient's mother had hypertension, and her father had died of a cerebral accident.

The blood pressure on admission was 190/110, the range during postural and cold tests being 190/140 to 158/102. The eye grounds showed narrowing of the retinal arteries. A 7-foot plate revealed the heart to be slightly altered in size and shape and the aorta to be tortuous. An electrocardiogram was within normal limits. The nonprotein nitrogen was 18 mg per 100 cc., and a phenolsulfonephthalein test showed 15 per cent excretion of the dye in 15 minutes and 75 per cent in 2 hours. The urine concentrated to 1028 and gave a ++ test for albumin, and the sediment showed rare red cells. Intravenous pyelograms showed prompt excretion and normal kidneys. On sedation the blood pressure fell to 128/90.

On March 23 the first stage of a bilateral lumbodorsal splanchnicectomy was performed on the right, the sympathetic trunk from the ninth dorsal to the third lumbar segment inclusive being excised. An identical operation was performed on the left 2 weeks later. The great splanchnic nerves were removed from the celiac ganglions to the midthoracic level on both sides. Reports of the biopsies from the kidneys revealed a Grade III chronic vascular nephrosis.

The patient became pregnant in July, 1943 and was readmitted in October for study and for a decision regarding the advisability of abortion. She complained of easy fatigability and nocturnal dyspnea. The blood pressure was 155/105 on admission but became normal during the hospital stay. The urine concentrated to 1030 and gave a + test for albumin, and the sediment contained occasional white cells. A phenolsulfonephthalein test showed 65 per cent excretion of the dye in 2 hours and the nonprotein nitrogen was 20 mg per 100 cc. It was decided that the pregnancy should be allowed to continue. The course of the pregnancy was uneventful, the blood pressure remaining below 155/100, the urine gave a + test for albumin or less. A female infant weighing 7 pounds, 10 ounces was delivered on March 10, 1944, following a normal labor.

CASE 10. A 34-year-old gravida II had first been seen in May, 1936, when she was 25 years old and single. Her complaints were headache and loss of vision. For 8 years she had had headaches that had become progressively severer. Eighteen months prior to admission she had been refused life insurance because of a systolic blood pressure of 170. The amaurosis had been present for 2 weeks. The patient's mother had died of cerebral hemorrhage, and an aunt of hypertensive disease.

The blood pressure on admission was 230/140. The heart was enlarged and abnormal in size and shape. An electrocardiogram showed slight changes, with left-axis deviation. The eye grounds were classified as Grade III and showed albuminuric retinitis. The patient could not distinguish fingers at 3 feet. The nonprotein nitrogen was 25 mg per 100 cc. A phenolsulfonephthalein test showed 18 per cent excretion of the dye in 15 minutes and 56 per cent in 2 hours. The urine concentrated to 1016 and showed a ++ test for albumin, and the sediment contained white cells in clumps and an occasional granular cast. The uterus was consistent with a 7½ months' pregnancy. The pregnancy was interrupted by an abdominal hysterotomy, a normal living female infant weighing 4 pounds, 8 ounces, being delivered.

Three months later the blood pressure was 158/100 and this dropped to 140/90 with bed rest. The urine concentrated to 1016 and gave a +++ test for albumin, and the sediment contained hyaline and granular casts.

In December the patient was readmitted with a blood pressure of 165/110. A two-stage operation was performed, the sympathetic trunk from the tenth to the twelfth dorsal segment, inclusive, being removed on each side. The great splanchnic nerves were removed on both sides from the celiac ganglions to the mid-thoracic level. The convalescence was uneventful.

Six years later the patient became pregnant for the second time. The blood pressure during the pregnancy varied between 140/80 and 120/80. The patient was symptom free and in good health throughout. The urine was free of albumin until the 7th month, when it gave a + test for albumin and the sediment showed white cells in clumps, which however, responded to sulfadiazine therapy. Two weeks prior to term

On May 9 the first stage of a lumbodorsal splanchnicectomy was performed, the right sympathetic trunk being removed from the ninth dorsal to the second lumbar segment, inclusive. The same operation was repeated on the left side two weeks later. The great splanchnic nerves were removed on both sides from the celiac ganglions to the midthoracic level. At operation the kidneys were noted to be scarred and contracted in an irregular fashion. Renal biopsies showed a Grade II chronic vascular nephritis on the left and a Grade III on the right. The patient was discharged on June 17, the blood pressure being 137/116.

Fourteen months after operation she was readmitted for study. Nausea and occasional dyspnea were the only symp-

urinary concentration was 1 027, with a + test for albumin, and the sediment was normal. Intravenous pyelograms were normal. On sedation the blood pressure fell to 132/90.

On April 1 the first stage of a splanchnicectomy* was performed, the left sympathetic trunk being excised from the tenth dorsal to the twelfth dorsal segment, inclusive. The same operation was performed on the right side 10 days later. The great splanchnic nerves were removed from the celiac ganglions to the midthoracic level. The patient was discharged on April 22 with a blood pressure of 115/86. She was seen at intervals during the next 4 years. The postoperative blood pressures were as follows: at 2 months, 120/80, at 5 months, 110/80, at 16 months, 108/80, at 24 months, 110/80;

FIGURE 2 Case 5 -

The blood pressure readings before lumbodorsal splanchnicectomy for malignant hypertension, associated with chronic bilateral pyelonephritis, are compared with those made fourteen months later (range shaded), at which time the patient was in the second month of pregnancy, whose subsequent course was uneventful.

toms. The blood pressure on admission was 132/90, the range during postural and cold tests being 158/110 to 120/106. A phenolsulfonephthalein test showed 55 per cent excretion of the dye in 2 hours. The nonprotein nitrogen was 16 mg per 100 cc, and the urine showed a specific gravity of 1.016 and a + test for albumin. In addition to the marked improvement in the blood pressure the heart had decreased in size, and the electrocardiogram showed a striking improvement with return to normal of the ST segments and T waves. The eye grounds showed minimal residual changes and were classified as Grade I.

The patient had become pregnant 1 year after operation. The pregnancy was uneventful, and she was delivered at term of a living infant, the blood pressure rising to 160/110 during labor (Fig. 2).

CASE 6. A 29-year-old gravida II had first been seen in March, 1937, at the age of 20 years. She had had known hypertension since her 12th year. During childhood she had had kidney trouble, the details of which were not known. For the previous eight years the blood-pressure range had been 182/112 to 240/116. The symptoms consisted of headaches of increasing severity, nervousness, vertigo and increasing fatigability.

The blood pressure on admission was 170/120, the range during postural and cold tests being 176/116 to 240/160. A 7-foot plate showed the heart to be normal in size and shape. The electrocardiogram was normal, as were the eye grounds. The nonprotein nitrogen was 24 mg per 100 cc. A phenolsulfonephthalein test showed 25 per cent excretion of the dye in 15 minutes and 62 per cent in 2 hours. The maximum

at 27 months, 129/90, at 42 months, 126/94, and at 50 months, 122/85.

The patient first became pregnant during the 6th year after operation. She was followed in this pregnancy through the 26th week, the blood pressure did not exceed 104/60, and the urine was normal. The patient was not seen for the remainder of this pregnancy, which resulted in a stillbirth, the details of which are not known.

The patient was next seen 8 years after operation during her second pregnancy, when she was 29 years old. The blood pressure during this pregnancy was as follows: at 4 months, 112/64, at 5 months, 100/70, at 6 months, 114/80, at 7 months, 110/60, and at 8 months, 126/68. The urine was negative for albumin throughout this pregnancy. A 7-pound female infant was delivered spontaneously on July 7, 1945. Six and 11 weeks post partum the blood pressures were 136/88 and 120/82 respectively.

CASE 7. A 29-year-old gravida I was first seen in 1938, when she was 24 years of age and single. Seven years previously, during a routine physical examination, an elevation

*In this case and in Case 10 a lower thoracic sympathectomy and splanchnicectomy were performed. These patients were operated on prior to October, 1938, when lumbodorsal splanchnicectomy was adopted as routine for hypertension. These were 2 of a few excellent results that one of us (R. H. S.) has noted following this operation for hypertension. Peet¹ reported the case of a patient with malignant hypertension who responded well to an operation of this type. The blood pressure of his 22-year-old patient prior to operation ranged from 230/170 to 280/190. Eight months later it was 136/90. The patient became pregnant 14 months after operation. Two months later the blood pressure rose to nearly preoperative levels and an abortion was performed. Four years and two months after operation the patient was well and the blood pressure was 139/101.

She was next seen in June, 1942, when she was 24 weeks pregnant. At that time a Diodrast-clearance test showed a marked reduction in renal blood flow to about a third of normal. The blood pressure was 132/92, and the urine was normal. The pregnancy continued uneventfully until the 4th week, when the blood pressure rose to 152/110 and the weight had increased to 234 pounds. The patient was admitted to the Boston Lying-in Hospital for study. The blood pressure responded well to bed rest (Fig. 3). The urea clearances during the 37th week of pregnancy showed 99 per cent and 104 per cent excretion of the dye respectively. During the following week the blood pressure rose to 164/120 and the urine showed a ++ test for albumin. Labor was induced by rupture of the membranes, and an infant weighing 6 pounds, 3 ounces, was delivered normally. Two and 6 weeks post partum the blood pressure was 110/84 and 122/84 respectively. The patient was evaluated 3 months after delivery when the blood pressure was 120/68, the range during postural and cold tests being 110/80 to 150/130. When she was admitted for study 34 months later the blood pressure was 176/118, the range being 146/110 to 210/164. The eye grounds showed marked improvement and were classified as Grade 1. An electrocardiogram was also improved and was reported as normal. At that time the patient weighed 200 pounds.

CASE 13 A 37-year-old gravida I had first been seen at the age of 33 when she was single. Because of weight loss and easy fatigability she had consulted a physician, who had found hypertension and referred her to the hospital for study in May, 1941. The blood pressure on admission was 210/150, with an average of 195/110 when the patient was resting in bed. The heart shadow was within normal limits. An electrocardiogram showed normal rhythm, inverted T waves in Lead 3 and a normal Lead 4. The eye grounds showed slight tortuosity and arteriovenous nicking. Pyelograms disclosed good excretion of the dye through both kidneys within 5 minutes. The urine concentrated to 1018 and contained no albumin, and the sediment was normal. A phenolsulfonphthalein test showed 35 per cent excretion of the dye in 20 minutes and 45 per cent in 1 hour. On sedation the blood pressure fell to 180/110. The patient was discharged with the diagnosis of essential hypertension.

In November, 1942, she was readmitted for splanchnicectomy. The laboratory data were essentially the same as those on the previous admission. A urea clearance showed a maximum excretion of 60 per cent with a volume of 145 cc. and of 68 per cent with a volume of 280 cc.

On December 1 a left lumbodorsal splanchnicectomy was performed, with excision of the sympathetic trunk from the tenth dorsal to the second lumbar segment, inclusive. On December 13 an identical operation was performed on the right side. On both sides the great splanchnic nerves were removed from the semilunar ganglions to above the mid-thoracic level. Biopsies taken from both kidneys revealed early renal arteriolar medial hyperplasia. After an uneventful convalescence the patient was discharged on January 11, 1943, with a blood pressure of 140/80.

The patient married in 1943 and became pregnant in December, 1944. The pregnancy was entirely normal. The highest blood pressure recorded was 138/85. The urine was consistently free of albumin, and the total weight gain was 18 pounds. She was delivered on October 9, 1945, of a living female infant and was discharged on the 14th post-partum day with a blood pressure of 132/90. Six weeks after delivery the blood pressure was 128/90.

CASE 14 A 39-year-old gravida V was admitted in January, 1943, complaining of headache and vertigo. She had developed hypertension during the first pregnancy 10 years previously. The hypertension had become progressively severer with three subsequent pregnancies.

Physical examination revealed an obese woman weighing 200 pounds. The blood pressure was 180/130, the range during postural and cold tests being from 170/106 to 218/132. The heart was not enlarged, but the aorta was tortuous. An electrocardiogram was normal. The urine showed a + test for albumin and a maximum concentration of 1020. The sediment was normal. The nonprotein nitrogen was 30 mg and the uric acid 2.9 mg per 100 cc., and the phenolsulfonphthalein test showed 30 per cent excretion of the dye in 15

minutes and 90 per cent in 2 hours. Intravenous pyelograms were normal. On sedation the blood pressure fell to 150/78.

On January 21 a right lumbodorsal splanchnicectomy was performed, the sympathetic trunk being removed from the ninth dorsal to the second lumbar segment, inclusive. On February 3 a similar operation was performed on the left, the sympathetic trunk being removed from the eighth dorsal to the second lumbar inclusive. The great splanchnic nerves were removed on both sides from the celiac ganglions to the mid-thoracic level. Biopsies taken at operation were reported as showing a Grade II chronic vascular nephritis. The patient was discharged on February 24 with a blood pressure of 155/105.

The patient conceived in December and experienced an uncomfortable pregnancy during which she gained 56 pounds. The blood pressure ranged between 150/70 and 150/90. The urine remained free from albumin. She was delivered on August 29, 1944, of a full-term, living infant. The blood pressure was 129/78, and the urine was normal when the patient was seen 18 months post partum.

Moderate to severe hypertension had been present in all cases until the patients had been treated by splanchnicectomy. Fourteen living infants were delivered, the oldest of which is now four years of age. One baby was stillborn, owing to premature separation of the placenta.

Three of the patients had so-called "malignant hypertension" prior to lumbodorsal splanchnicectomy. They responded favorably to operation and tolerated subsequent pregnancy well. Both mothers are living and well, having exceeded the average life expectancy for patients with malignant hypertension, and having living children. This experience is regarded as unique. In 1 case the pregnancy was completely uneventful, and in the other a transient rise in blood pressure associated with the occurrence of a + test for albumin necessitated delivery a few days prior to full term. In the third case the pregnancy was uneventful, but the puerperium was complicated by a psychosis.

The other 11 patients had severe essential hypertension, with or without chronic pyelonephritis. These patients are also living and well following pregnancy. The hypertension is much improved over that prior to splanchnicectomy. There is as yet no definite evidence that pregnancy has materially affected the postoperative course of the hypertensive process in these cases. In 5 cases increasing hypertension associated with increasing albuminuria occurred during the third trimester, necessitating delivery prior to full term. In no case did the hypertension increase prior to the seventh month of pregnancy.

It should be emphasized that in these cases, as in patients who have not had a previous lumbodorsal splanchnicectomy, one should not procrastinate when the signs of toxemia appear. The established and accepted criteria for termination of pregnancy should be closely observed.

It seems most unlikely that the majority of these patients could have obtained living children without suffering material cardiovascular damage or an increase in the severity of the hypertension following pregnancy had not lumbodorsal splanchnicectomy

the patient was delivered by a repeat hysterotomy of a female infant weighing 6 pounds, 5 ounces. The puerperium was uneventful. Six weeks post partum the blood pressure was 136/88, and the urine was free of albumin.

CASE 11 A 33-year-old gravida II was admitted in September, 1940, with the diagnosis of malignant hypertension and pyelonephritis. She had been known to have hypertension for 2 years. The family history was irrelevant. Six years before admission, in the 8th month of the first pregnancy, pyelitis, hypertension, coma and convulsions had developed. This pregnancy had been terminated by an abdominal hysterotomy at the 36th week. For 2 years prior to

months postoperatively, when the patient was 1 month pregnant, the blood pressure was 98/58, and the urine was normal. The pregnancy was entirely uneventful. The blood-pressure range was 115/80 to 150/98. The urine remained free of albumin, and the total weight gain was 17 pounds.

Sixty-four months after operation, when the patient was 2 weeks from term, a repeat hysterotomy was performed under spinal anesthesia. A female infant weighing 7 pounds was delivered. The surgical convalescence was uneventful, and the patient was discharged on the 14th postoperative day, the blood pressure being 120/84 and the urine free of albumin. Unfortunately, the patient manifested symptoms of a puerperal psychosis beginning on the 10th post-partum day. These

FIGURE 3 Case 12

The average blood-pressure levels are charted for twenty-six days prior to delivery. During that time the patient was hospitalized because of a reading of 152/110. She responded well to rest. The membranes were ruptured ten days prior to term because the blood pressure had risen to 168/120. Five weeks following delivery the level was 125/80. This patient had malignant hypertension prior to lumbodorsal splanchnicectomy.

admission the patient had had frequent headaches, tinnitus and transient paresthesias.

The blood pressure on admission was 240/150, the range during postural and cold tests being from 138/112 to 240/150. The heart was normal in size and shape. An electrocardiogram was typical of hypertension. The eye grounds showed marked hypertensive changes with hemorrhages, exudate and advanced changes in the retinal arteries and marked bilateral papilledema. The nonprotein nitrogen was 21 mg per 100 cc, and a phenolsulfonephthalein test showed 25 per cent excretion of the dye in 15 minutes and 55 per cent in 2 hours. The maximum urine concentration was 1030. There was a + test for albumin, and the sediment was normal. Intravenous pyelograms were normal. On sedation the blood pressure fell to 126/98.

The first stage of the splanchnicectomy was performed on October 2. The left sympathetic trunk was excised from the ninth dorsal to the second lumbar segment, inclusive. At the second stage, on October 16, the right sympathetic trunk was removed from the ninth dorsal to the first lumbar, inclusive. The great splanchnic nerves were removed on both sides from the celiac ganglions to the midthoracic level. No biopsies were taken, but at operation both kidneys were described as diffusely scarred and contracted in an irregular fashion, the gross appearance being characteristic of chronic pyelonephritis. The patient was discharged on October 30, when the blood pressure was 124/95.

Twenty-seven months after operation the blood pressure was 124/91, the range during postural and cold tests being 140/108 to 112/82. Eleven months later the blood pressure was 120/76, and the range 150/112 to 115/68. Fifty-five

months postoperatively, when the patient was 1 month pregnant, the blood pressure was 98/58, and the urine was normal. The pregnancy was entirely uneventful. The blood-pressure range was 115/80 to 150/98. The urine remained free of albumin, and the total weight gain was 17 pounds.

CASE 12 A 36-year-old gravida V was admitted in February, 1941, with a diagnosis of malignant hypertension which had developed during the third pregnancy in 1935. The fourth pregnancy had been interrupted at 4 months because of severe hypertension.

The blood pressure on admission was 206/130, the range during postural and cold tests being 164/110 to 220/160. The eye grounds showed changes indicative of the malignant phase of hypertensive disease. There were marked abnormalities of the retinal arteries, with occasional hemorrhages and associated papilledema. A 7-foot plate showed the heart to be enlarged and abnormal in shape, with a tortuous aorta. An electrocardiogram was consistent with mild hypertensive heart disease. The nonprotein nitrogen was 15 mg per 100 cc, and a phenolsulfonephthalein test showed 40 per cent excretion of the dye in 15 minutes and 75 per cent in 2 hours. The urine contained no albumin, and the sediment was normal, as were intravenous pyelograms.

On February 25, 1941, at the first stage of a lumbodorsal splanchnicectomy the sympathetic trunk from the tenth dorsal to the first lumbar segment, inclusive, was removed on the right. Two weeks later, at the second stage, the left sympathetic trunk from the ninth dorsal to the first lumbar, inclusive, was removed. Biopsies from both kidneys showed a chronic Grade II vascular nephritis. After a normal convalescence the patient was discharged on March 29, with a blood pressure of 135/95.

century, when Cushing and his pupils made their far-reaching studies of the hypophysis and its neighborhood, that the notion of metabolic control by brain centers gained any real acceptance. The present-day concept of this influence of the central nervous system is given by Ranson⁴ as follows:

Resting on the optic tract lateral to the chiasm is a compact group of rather large cells, the supra-optic nuclei. Fibres arising in this nucleus along with some other fibres of hypothalamic origin run along the infundibulum to the posterior lobe of the hypophysis. Through this hypothalamo-hypophyseal tract the hypothalamus is in position to influence the functions of the hypophysis. One or the other of these two structures or both together exert an important control over the utilization of sugar, fat and water in the body.

To this Wiggers⁵ adds:

The structures of the hypothalamus are head centers for the sympathetic nervous system. Stimulation or lesions in this region may cause alterations in heart rate and blood pressure, sweat secretion, carbohydrate protein and fat metabolism, temperature regulation, evacuation of bladder and rectum, polyuria, dilatation of the pupils, widening of the palpebral fissures and bulging of the eyeballs.

Changes in body metabolism due to tumors involving this region are well recognized. Disorders following encephalitis of this area of the brain are not uncommon; comparable changes following trauma, however, are much less frequent, and it is with these disturbances of metabolism associated with head injuries that the present paper is concerned.

That such changes do occur has been noted by several writers. Bailev,⁶ in 1906, reported the appearance of transient glycosuria, lasting from twenty-four hours to five or six days, in patients with head injuries. This was found with fractures of the vault or of the base, and in some patients with no known fracture. In some cases the glycosuria was accompanied by an increase in the amount of urine, and in others polyuria existed without sugar. In 1940 Gross and Ehrlich⁷ mentioned glycosuria due to hypothalamic damage and stated that diabetes insipidus might arise from the same cause.⁸ Such injury was considered likelier to occur in the presence of fractures of the middle cranial fossa. Rowbotham,⁹ in 1942, gave the following interesting description:

Traumatic diabetes insipidus usually declares itself early in convalescence though it may not appear till several months after the injury. The outstanding symptom in this condition is insatiable thirst with a desire for water to assuage it. In severe cases a patient will drink 1 or 2 pints of water at a time and has to take copious supplies to bed with him as he so often awakens in the night and wants to drink. Fluids taken by mouth are rapidly excreted by the kidneys so that a patient tends to lose weight rather than to become waterlogged. Severe headaches, loss of physical energy, and mental depression are commonly associated with the symptoms of thirst. One young patient of mine who had been severely concussed and whose skull had been fractured through the pituitary fossa needed at least 12 pints of fluid in the day to satisfy his thirst, and once drank as many as 15 pints. The amount of water he passed was graphically described by his mother as being worthy of a donkey. In fact a large bucket was left under the bed for his use as his nocturnal peripatations used to disturb the whole household. This disturbance of

water metabolism was readily controlled by hypodermic injections of 0.5 cc. of pituitin night and morning. In six months after the injury this young man made a complete recovery. The tendency in all cases of traumatic diabetes insipidus is toward spontaneous cure. It is useless to restrict the amounts of fluids taken in an attempt to control the diabetes because this only leads to dehydration and toxemia. Usually injections of pituitin will keep a patient's thirst under reasonable control until spontaneous cure of the diabetes results. Severe and persistent cases may necessitate a total thyroidectomy as suggested by the work of Mahoney and Sheehan.

All these are cases of disturbed use of sugar and water in the body. The only example of upset fat metabolism of which I have found a report thus far is also given by Rowbotham.¹⁰

A pathological increase in weight due to excessive deposits of fat occasionally results from a basal injury, as evidenced by the case of a late Professor of Surgery in Manchester who fell from a horse and fractured the base of his skull. Following the injury, he became extremely stout, and this stoutness was associated with very definite dispositional changes.

The small number of reports of actual patients suffering from these disorders indicates either a lack of interest in these conditions or a considerable rarity of occurrence. My interest was aroused by the onset of severe diabetes insipidus in one patient and of an unusual disturbance of fat metabolism in another, in both, the findings were so striking that they demanded attention, stimulating a search for similar disorders in other patients. In the treatment of over 2500 patients with head injuries in the past ten years 7 cases of metabolic disturbance, 2 of sugar metabolism, 4 of water metabolism and 1 of fat metabolism have been noted, none involving protein metabolism have been recognized. It is not at all unlikely that many minor disorders have been overlooked, since interest was only recently directed to this subject. A careful study of these factors in all patients is now being made, in the hope that a reasonably accurate estimate of their incidence will be possible.

SUGAR METABOLISM

Only 1 case of transient glycosuria similar to that reported by Bailev⁶ has been observed. This occurred in a patient who later developed diabetes insipidus and whose record is more fully discussed in the consideration of water metabolism. Since many of the patients were given glucose by vein soon after the injury, some minor disturbances may well have been concealed. Another case of upset sugar metabolism was the following:

A 27-year-old man was admitted to the hospital on April 28, 1945 following an automobile accident in which he was said to have struck his head on some part of the car. On admission he was in severe traumatic shock and was in coma, with evidence of serious generalized brain damage but without clinical signs of skull fracture. It was learned that he was mildly diabetic and had been taking 20 units of protamine insulin daily. In view of this, the control of the diabetes was kept in mind from the start, and the Medical Service took over that part of the problem. There was no indication that the coma was in any way due to diabetes — the urine showed a +++ test for sugar and no acetone, and the blood

tomy been performed. In 1 case the operation was performed during the first trimester, so far as we know this is the first case on record treated in this manner. In the other cases the interval between operation and pregnancy ranged from three to ninety-six months, the average being thirty months.

CONCLUSIONS

It is known that lumbodorsal splanchnicectomy is a useful therapeutic measure in the treatment of hypertension and hypertensive cardiovascular disease.

Following a satisfactory response to operation, pregnancy, if carefully supervised, appears to be safe and permissible.

The experiences presented above lead us to believe that following this operation certain hypertensive women may be able to tolerate pregnancy, which

would otherwise be impossible or extremely hazardous. This is particularly true in the younger age group with severe essential and even malignant hypertension.

DISTURBANCES OF METABOLISM ASSOCIATED WITH HEAD INJURIES*

WILFRED PICKLES, M.D.†

PROVIDENCE, RHODE ISLAND

Diabetes is a wonderful affection, not very frequent among men, being a melting down of the flesh and limbs into urine. Its cause is of a cold and humid nature as in dropsy. The course is the common one, namely the kidneys and bladder, for the patients never stop making water, but the flow is incessant, as if from the opening of aqueducts. The nature of the disease, then, is chronic, and it takes a long period to form, but the patient is short-lived, if the constitution of the disease be completely established, for the melting is rapid, the death speedy. Moreover life is disgusting and painful, thirst, unquenchable, excessive drinking, which however, is disproportionate to the large quantity of urine, for more urine is passed, and one cannot stop them either from drinking or making water. Or if for a time they abstain from drinking, their mouth becomes parched and their body dry, the viscera seem as if scorched up, they are affected with nausea, restlessness, and a burning thirst, and at no distant time they expire. Thirst, as if scorched up with fire. But by what method could they be restrained from making water? Or how can shame become more potent than pain? and even if they were to restrain themselves for a short time, they become swelled in the loins, scrotum, and hips, and when they give vent, they discharge the collected urine, and the swellings subside, for the overflow passes to the bladder. Hence the disease appears to me to have got the name diabetes, as if from the Greek word *διαβητης* (which signifies a siphon), because the fluid does not remain in the body, but uses the man's body as a ladder (*διαβαλῶν*)‡ whereby to leave it. The cause of it may be that some of the acute diseases may have terminated in this, and during the crisis of the disease may have left some malignity lurking in the part. It is not improbable also, that something pernicious, derived from the other diseases

which attack the bladder and kidneys, may sometimes prove the cause of this affection.

THIS vivid description was written by Aretaeus, the Cappadocian,¹ who lived around 200 A.D. and whose careful accounts of pathologic conditions rank next to those of Hippocrates. It is interesting to note that this picture includes features of diabetes insipidus, diabetes mellitus and nephritis, this confusion persisted for many years. In the seventh century the Brahmin physician Susruta recognized the "honey urine," and four hundred years later Avicenna noted the sweet taste of the urine. It was not until the seventeenth century, however, that Thomas Willis made a clear distinction between diabetes mellitus and diabetes insipidus, followed in a few years by Johann Brunner's early experimental proof of the relation of the pancreas to diabetes mellitus. The relation of the brain to these processes was indicated by Claude Bernard's puncture of the fourth ventricle with resultant glycosuria in 1849. Bramwell,³ in 1888, stated as follows:

Tumours of the pituitary body are in many instances attended with an excessive development of the subcutaneous fat, and in some cases with the presence of sugar in the urine or with simple polyuria (diabetes insipidus). Whether these symptoms are due to the fact that the pituitary body is itself diseased, or whether, as seems more likely, to the secondary results which tumours in this situation produce in the surrounding cerebral tissue, has not yet been decided.

These investigators were apparently well ahead of their times, for it was not until early in the present

‡This Greek word might be better translated literally "something to step through." The Latin translation is "quia humor in corpore non remanet, sed homine tanquam canali quodam, ad effluendum utitur" — that is "because the fluid does not remain in the body but uses the man as a sort of water pipe for flowing off."

of thyroid overactivity, but the basal metabolic rate was -24 per cent. This excess appetite has decreased, but 4 weeks ago he began to drink large amounts of water and other fluids, which failed to satisfy his thirst, and passed large quantities of urine. According to home records whose accuracy may be open to some question, the intake was from 5000 to 6000 cc., and the output 7000 to 8000 cc. Examination of the urine showed a specific gravity of 1.001, with no albumin or sugar and with no abnormal elements in the sediment. Examination of the blood showed normal values for urea nitrogen and sugar, with that for cholesterol slightly elevated to 252 mg per 100 cc. The patient has been treated with injections of Pituitrin, and a week ago the intake and output were approximately 2000 cc. each, and the specific gravity of the urine was 1.010. It seems not unlikely that he has metabolic disorders involving more than the use of water, and he is being studied with this possibility in mind.

FAT METABOLISM

The single case of disturbed fat metabolism after head injury was as follows

In February, 1945, a 47-year-old shipyard foreman entered the hospital about two weeks after a fall in which he had struck the back of the head. There had been a short period of unconsciousness followed by severe occipital headache and two episodes of vomiting. He then became lethargic and felt weak, was unable to concentrate and had partial amnesia for recent and remote events. Prior to the accident he had had charge of the work on three different ways at the yard, his duties involving constant climbing and physical activity, and he had lost no time from work. He had worked many hours overtime and felt somewhat tired, but his superiors considered his work excellent.

Physical examination showed a healed laceration about 5 cm. long, in the occipital region. The right pupil was slightly smaller than the left, both reacted sluggishly to light, the left a little more slowly than the right. The optic disks were normal, there was slight weakness of the right masseter muscle and of the right facial muscles, the superficial reflexes were diminished on the right and the deep reflexes were diminished on the left. X-ray films of the skull, including particular examination of the sella showed no fracture. Lumbar-puncture findings were within normal limits.

It was at first thought that the patient might have a subdural hematoma, but the symptoms improved so much on bed rest that exploration was considered inadvisable. In the course of a routine examination of the blood he was found to have a grossly visible lipemia, and studies to determine its cause were begun. The urine was normal except for a slight trace of protein and a few granular hyaline casts. Examination of the blood showed normal red-cell and white-cell counts and differential distribution and a normal amount of hemoglobin, the urea nitrogen, total protein and glucose levels were normal. The total fat in the blood was 5 per cent (normal, 0.5 to 0.7 per cent). The cholesterol was 584 mg per 100 cc. (high normal, 220 mg). The total blood lipid was 44 per cent, and the lipid phosphorus was 21.5 mg per 100 cc. The prothrombin time and icteric index were normal, and a glucose-tolerance test was also normal. A hippuric acid test was 145 per cent of normal. There was no evidence of tachyarrhythmias.

On repeated examinations the lipemia persisted and the cholesterol stayed at about the same level. After careful consideration, the Medical Service concluded that the patient had a lipemia of unknown origin. A well known authority on fat metabolism saw the patient and could give no explanation for the lipemia other than the trauma, he believed that if the disturbance in the use of fat disappeared as the head injury cleared it would confirm the impression that the condition was due to brain damage. The neurologic signs subsided slowly, and the patient was discharged at the end of 1 month complaining of occasional headaches, irritability, depression, muscular weakness and easy fatigability.

His condition has been followed since that time by clinical examinations and cholesterol determinations. In April, 1946, the cholesterol was 680 mg per 100 cc., in May it was 432 mg, and in July it was 496 mg. At that time the patient was

put on a diet low in cholesterol, and by October the cholesterol had dropped to 284 mg per 100 cc., he was much less irritable and was able to undertake some physical activity without marked fatigue. Eleven months after the accident the cholesterol was 176 mg per 100 cc. and the patient felt much better. With the withdrawal of most of the dietary restrictions the cholesterol rose to a little above normal levels, but it has now leveled off. The patient's strength is returning, his disposition is good and he is able to work.

In this case as in diabetes insipidus, it seems likely that treatment served to relieve symptoms by lowering the amount of cholesterol in the blood without actually affecting the course of the disease.

SUMMARY

Seven cases of metabolic disturbance associated with head injuries are presented for consideration. There is, of course, no real proof that any one of these examples of abnormal metabolism was actually due to a traumatic lesion of the hypothalamic region, no study was made prior to the injury, there was no death, and tissue examination was not possible. The patients represented a group of supposedly normal people who suffered head injuries involving slight to severe brain damage, who then, at periods varying from a few hours to three years later, developed disturbances in the use of sugar, water and fat such as those known to occur when the hypothalamus is injured, and whose disorders cleared up as the head injury healed. It thus seems reasonable to suppose that brain damage was a causal factor. A realization of the possible occurrence of such upsets, and a continued search for them will, in all probability, result in more frequent recognition and a better understanding of these interesting disturbances of metabolism.

DISCUSSION

Dr. DONALD MURRO (Boston). This excellent and well documented paper deserves more than passing notice. The subject is extremely important and so far as I know, nothing so thorough as this has previously been published.

a study of this aspect of the epidemiology was instituted. Although influenza was prevalent throughout all schools in Needham, the study reported in this paper was limited to the high school, the junior high school and one of the elementary schools (Avery School).

With the co-operation of the local school and health-department nurses, visits were made between December 13 and 16 to the junior high school and to the homes of some of the pupils who were absent because of symptoms of influenza. At that time detailed histories were obtained, physical examinations were done on a number of the pupils who were acutely ill and blood was drawn for serologic studies. Throat garglings were also obtained from a few patients who were acutely ill with typical symptoms of clinical influenza and with temperatures of 101°F or higher. Histories concerning recent illness and blood for serologic studies were also obtained from as many household contacts as possible. A second visit was made to each of the same homes between December 29 and January 2, when second samples of blood were drawn and individual histories taken from the patients and the household contacts.

Epidemiologic data concerning illnesses and absenteeism during the period of the epidemic were obtained by means of a questionnaire given to each student in the three schools chosen for the study. Again, the school and local health-department nurses participated by explaining to teachers, parents and pupils the purpose of the investigation and by distributing and collecting the questionnaires. The school records were also examined for detailed information concerning absenteeism.

In an attempt to differentiate cases of common cold and other illness not related to influenza, specific information was sought in the questionnaire concerning such symptoms as malaise, headache, cough, coryza, sore throat, pain in the eyeballs, back and extremities, vomiting and diarrhea. There were other questions regarding date of onset, duration of symptoms, the presence or absence of fever and the total duration and degree of temperature rise. Patients presenting a majority of the symptoms mentioned above, in addition to a fever of at least twenty-four hours' duration, were tabulated as cases of influenza. Fortunately, the clinical picture was quite definite, the onset was sudden, prostration marked and in at least half the cases studied the duration of illness was four days or longer. The incidence of the common cold was low in this community during the time of the epidemic.

LABORATORY STUDIES

The methods used in the laboratory investigations and the results obtained are presented in detail elsewhere.¹¹ Attempts to isolate viruses from the throat washings of the patients from Needham were unsuccessful at first. Two strains of virus, however, were readily established in other cases that were

studied at that time, and a third strain was subsequently isolated in one of the Needham cases. These epidemic strains were identified as influenza B and were used for the serologic studies along with the PR8 strain of influenza A virus and the Lee strain of influenza B virus. Tests for inhibition of chicken erythrocyte agglutination and complement-fixation tests were done on serums taken from patients during the acute and convalescent phases and on those

TABLE 1 *Results of Tests for Influenza Antibodies in Cases and Household Contacts*

*An additional case showed a rise by complement fixation but not by inhibition of agglutination.

obtained at the same time from the household contacts. The results of the serologic tests are summarized in Table 1.

Of the 19 typical cases of clinical influenza included in this study 16 yielded convincing evidence of infection with influenza B virus by significant, and in most cases marked, rises in the titers of antibodies for the Lee strain and for the epidemic strains but not for the PR8 strain. The 3 cases in which no rise in antibodies was demonstrated for any of the viruses used were all in members of the same family, and these were the only persons studied in that household.

All the household contacts who did not have symptoms of clinical influenza failed to show a significant — that is, a fourfold — rise in titer of antibodies for either the PR8 strain of influenza A virus or the Lee strain of influenza B virus. The serums of these persons were also tested with the epidemic strains, and no significant rise in titer of antibodies for any of them was demonstrated. Included among the contacts were 4 subjects who had coryza without fever or systemic symptoms and were regarded as having the common cold, 4 others who had low-grade fever and gastrointestinal symptoms, mostly diarrhea, and 12 healthy persons who had had no recent illness. Only 2 of the contacts were school children, the others were adults — most of them parents of the patients with influenza.

EPIDEMIOLOGY

During the interval December 2–21 a total of 484 cases of influenzalike infection occurred in the three schools included in the study. The attack rate was highest — 53.7 per cent — in the junior high school, and lowest — 24.4 per cent — in the senior high

The problem of the initiation of diabetes mellitus by trauma to the head is brought up from time to time before compensation boards in various states, and I happen to have been involved in such a discussion. On a search for authoritative statements regarding whether or not trauma to the head actually caused diabetes mellitus, it was impossible to find any really substantive statements. Now we have an authority that we can quote.

In connection with this experience, I called Dr. Elliott P. Joslin to find out whether he had any knowledge about the

causal relation between head injury and diabetes mellitus. He stated that, so far as he knew, there is no such relation. In my experience, I have not knowingly seen a patient who has sustained a head injury and who, as a result of that injury, has had diabetes mellitus. The combination is not frequent.

Diabetes insipidus, of course, is a different story, although a relatively rare disease, it is, again, extremely useful to have these cases on record, particularly when they have been worked up so carefully.

AN OUTBREAK OF INFLUENZA B INFECTION*

Epidemiologic Observations

A. DANIEL RUBENSTEIN, M.D.,† EDWIN M. ORY, M.D.,‡ MANSON-MEADS, M.D.,§ AND
MAXWELL FINLAND, M.D.¶

BOSTON

ALTHOUGH much knowledge concerning the epidemiology of influenza has been acquired over the years, more specific information has awaited the isolation of the etiologic agents. The discovery of the influenza B virus in 1940 simultaneously by Francis¹ and Magill² greatly facilitated the researches on the epidemiology of this disease. Nevertheless, data concerning the transmission of influenza B have not accumulated at a rapid rate. In some outbreaks it has been difficult or impossible to isolate the influenza B virus, and identification of cases in such circumstances necessarily depended on serologic studies. Furthermore, in extensive epidemics, it is not often practical to obtain acute and convalescent blood specimens from more than small samples of the population being investigated.

It has been shown that influenza B infection occurs as both an endemic and an epidemic disease. In Argentina, for example, sporadic cases of influenza B infection appeared in 1941 over a period of several months (June to October). This was in contrast to a sharp outbreak of influenza A infection during the previous year.³ Beveridge and Williams⁴ noted the sporadic occurrence of influenza B infection in Australia from June to September, 1943. Hare et al.⁵ reported a high incidence of upper respiratory infection in various localities in Canada. Serologic evidence indicated that 23 per cent of the cases were due to influenza B virus. Localized outbreaks, on

the other hand, have been reported from a convalescent home¹ and from a hospital for mental diseases. In the latter institution 71 patients out of 144 developed influenza B infection. In one unit the combined incidence of clinical and subclinical influenza was 20 per cent.

Influenza B may occur either alone or in association with influenza A. Lennette et al.,⁷ in a study of twelve outbreaks of influenza, found cases of influenza A infection in all but two epidemics, whereas cases of influenza B infection were encountered in only five epidemics. Influenza of unknown etiology occurred in each epidemic and accounted for 11 to 80 per cent of all the cases.

There is some statistical evidence that widespread epidemics of influenza B infection have occurred at intervals of four to six years.⁸ Francis⁹ suggested a four-year cycle on the basis of two known widespread epidemics of influenza B infection in 1936 and 1940.

Beginning in mid-April, 1945, small outbreaks of influenza B infection were reported from many areas in and outside the United States and were identified serologically or by virus isolation.¹⁰ Late in November and in December of that year an increased incidence of clinical influenza was noted in several communities in the Greater Boston area. Although the infection was generally prevalent throughout the entire area, there was considerable variation in incidence from one community to another.

PURPOSE AND METHODS

During the second week of December, 1945, our attention was called to reports indicating that influenza had assumed epidemic proportions in the schools of Needham, Massachusetts. In the junior high school, with an enrollment of 577 children, 50 per cent absenteeism had occurred. In the absence of detailed information in the literature concerning the transmission of influenza B infection in schools,

sions during the peak of the epidemic less than a third of the children out of school were absent because of influenza.

In all three schools the proportion of total absenteeism due to influenza increased as the epidemic progressed. On December 4 the percentages for the Avery School and the senior high and junior high schools were 4.0, 10.7 and 37.5 respectively, and ten days later they had risen to 31.0, 37.4 and 73.0 in the same order. In general the figures for percentage absenteeism due to influenza were high in the junior high school, low in the Avery School and intermediate in the high school. No other contagious disease was prevalent in the three schools during the period of the study. Hysteria on the part of parents who did not permit their children to attend school lest they be exposed to the infection was responsible for a large proportion of absenteeism due to causes other than influenza.

DISCUSSION

It has been stated that the virus of influenza B spreads less rapidly than that of most A strains and that ordinarily it does not produce extensive outbreaks.¹² The high incidence of this infection in the Needham schools is evidence that it may at times resemble influenza A virus in its rate of transmission. Well defined epidemic curves were noted in the three schools selected for the study and also in the individual grades of the junior high school. High attack rates prevailed in individual classrooms and throughout the school system.

The incidence of infection in the junior high and Avery schools was significantly higher than that in

to infection was present in each. It may therefore be postulated that the variation in age distribution was the prime factor in the difference between rates.

the senior high school. Both the senior and junior high schools were attended by pupils living throughout the entire community, and since cases were reported from every homeroom and grade in both schools, it is apparent that opportunity for exposure

to vaccination against influenza. It is apparent that in a susceptible population, large numbers of children will develop influenza B infection following adequate exposure and that an effective immunizing agent would be of value in diminishing school absenteeism.

school, the difference being significant statistically. The standard deviation of the difference between these rates is 29.3 ± 2.8 . The difference in the rates between the junior high and Avery schools, however, was not found to be statistically significant. The

forty-eight hours (Fig 2), indicating widespread dissemination of infection through all three grades at about the same time. Of 120 cases in the eighth grade 81, or 67 per cent, appeared in the seven-day period from December 7 to 13. In the ninth grade 64 of 109 patients, or 59 per cent, became ill during the same week. Although there was considerable variation in the curve for each grade, it is apparent that a fairly well defined rise and fall occurred in each group.

The attack rates in individual classrooms varied from 38.5 to 82.9 per cent. Out of seventeen classrooms in the junior high school, the attack rate was

FIGURE 1 Distribution of Cases in All Schools according to Date of Onset

standard deviation of the difference between the latter rates is 9.2 ± 5.0 (Table 2).

The distribution of cases in the three schools according to the date of onset is presented in Figure 1.

TABLE 2 Attack Rates in Three Schools

Totals	1191	484	
Average			40.6 ± 1.42

The day of highest incidence in the junior high school preceded that in the senior high and Avery schools by a week. A second peak occurred in the junior high school at the time of highest incidence in the other two. All peaks occurred at or just after a week end. A sharp epidemic curve was noted in all three schools.

The peak in the seventh, eighth and ninth grades of the junior high school occurred within a period of

FIGURE 2 Distribution of Cases in the Junior High School according to Date of Onset

50 per cent or higher in nine and less than 40 per cent in three (Table 3). The attack rate for the entire school was 53.7 per cent, 310 children out of the total of 577 enrolled having developed clinical influenza from December 2 to 21.

Total absenteeism as compared with that caused by influenza is demonstrated in Table 4. In the junior high school at the height of the epidemic a major proportion of children absent from school were ill with influenza. On December 10, for example, 123 (78.3 per cent) of 157 absentees were ill with influenza and only 34 pupils (approximately 6 per cent) of the total enrolled were absent for causes other than influenza.

In the senior high school, where the attack rate was lower, the proportion of children absent because of influenza was considerably less than that in the junior high school. From December 10 to 18, at the very height of the epidemic, the percentage of absenteeism due to influenza varied from 14.8 to 54.5.

In the Avery School the bulk of absenteeism was due to causes other than influenza. On several occa-

MEDICAL PROGRESS

PEDIATRICS*

MEMBERS OF THE STAFFS OF THE CHILDREN'S AND INFANTS' HOSPITALS†

BOSTON

THE justification for considering pediatrics a specialty does not arise from its concern with a particular type of disease or with the special techniques necessary to deal with a particular region of the body, but rather from the nature of its patients, who are distinguished by an outstanding characteristic—they are constantly growing. The aim of the pediatrician is to assist, to the limit of his abilities, this process of growth so that his patient may increase "in wisdom and in stature." Thus, the basic goal of pediatrics is preventive, although it is concerned with curative medicine and surgery, and its scope naturally extends from the time of conception until the cessation of physical growth. This broad view has added to the concerns of the pediatrician the antenatal period on the one hand, when he must work with the obstetrician, and the period of adolescence on the other, when his interests begin to merge with those of the internist and gynecologist.

By the application of knowledge in the fields of nutrition and infectious disease, pediatricians and public-health workers have been remarkably successful in assisting the physical growth of children. This success only emphasizes their obvious failures. Accidents, particularly those due to automobiles, are the major cause of death in childhood, and yet physicians and public-health workers have given their prevention little thought. It is in the guidance of mental and emotional development that the shortcomings of present knowledge and practice are most apparent. The ultimate standard by which the success or failure of pediatrics must be judged is the extent to which its charges become well integrated, responsible citizens when they graduate to adult life. The prevalence of psychoneurotic disorders as a cause of rejection in Selective Service examinations and of disability in American troops has clearly indicated deficiencies in the field of

mental hygiene.¹ Success in this field will depend, as it does in that of physical hygiene, on a basic understanding of the normal pattern of growth and development.²

Although the care of both healthy and sick human beings in the growth period has become the special concern of pediatrics, it is doubtful whether there are sufficient pediatricians to provide for more than a fraction of the child population. The extent to which present facilities for the medical care of children are adequate and to which services to children are provided by pediatricians, by general practitioners or by other types of professional workers will be known when the present study of child health services³ is completed. This study, organized by the American Academy of Pediatrics, with the co-operation of the Children's Bureau and the United States Public Health Service, represents a laudable attempt by a voluntary medical organization to obtain the necessary information on which to base future plans for the improvement of medical care.

It is debatable whether the attempt should be made to provide pediatricians for all children. In society the unit is not the child but the family, all of whose members are involved whenever illness strikes anyone in the group. It is interesting to compare the emphasis on specialization in this country to the policy in Great Britain, where, traditionally, the pediatricians have been a small group of consultants, routine child care being given on the preventive side by public-health workers and on the curative side by general practitioners. In a recent report, the Pediatric Committee of the Royal College of Physicians of London⁴ states

The present policy of having two groups of medical personnel, the one engaged in preventive and the other in curative work, is good neither for the child nor the doctor. A long-term policy should aim at making the general practitioner primarily responsible for the medical care of the child, in both the prevention and treatment of disease, since he is the one best fitted to give this service in the home.

Ultimately, the normal channel through which the family seeks medical advice in health as well as the sickness should be by consultation with the family general practitioner.

*From the Department of Pediatrics and the Department of Orthopedics, Harvard Medical School and the Children's and Infants' Hospitals.

†Those who contributed to the preparation of this report were Randolph E. Byers, M.D., Bronson Crothers, M.D., Gretchen Hutchins, M.D., Charles A. Janeway, M.D., Meyer Karp, M.D., William G. Lennox, M.D., Charles U. Lowe, M.D., Charles D. May, M.D., Clement A. Smith, M.D., and David R. Utt, M.D.

The data presented above offer some evidence of the reliability of absenteeism reports as an indication of the prevalence of influenza. Whatever the reason for the observed differences in the percentage of absenteeism due to influenza among the three schools, it appears that total absenteeism is sometimes a poor index of the prevalence of influenza.

Some information concerning the occurrence of subclinical infection with influenza B virus has been acquired from previous studies. Stuart-Harris et al.¹³ reported the cases of several patients who developed neutralizing antibodies following exposure to influenza B infection and remained symptom free. In 1944 Francis¹⁴ reported that 11 of 30 uninoculated controls without recognizable illness developed a significant rise in antibody level after a period of 14 days.¹⁴ During the course of an epidemic of influenza B infection in a mental institution, Nigg and her associates⁶ found that 14 per cent of blood specimens taken from 77 contacts who had not been ill showed positive complement-fixation reactions for influenza B virus in a dilution greater than 1:5.

In the present study significant rises in antibody titers for the influenza B viruses were demonstrated only in the blood of persons who had characteristic symptoms of infection. Identical results in this respect were shown in most cases both by the complement-fixation reaction and by tests for inhibition of chicken red-cell agglutination.

The apparent disparity between this and the previous studies noted above may have been a matter of strain peculiarity. It must be recalled, however, that the sample studied was small and that virus isolation was not attempted on healthy contacts. At any rate, significant antibody responses were demonstrated only in patients with clinical evidence of infection, and the existence of healthy carriers could not be postulated on the basis of serologic evidence alone.

It is noteworthy that of 19 persons considered to be ill with influenza, laboratory studies confirmed the clinical diagnosis in 16. In only 3 cases, all of which occurred in one family, did serologic tests fail to tally with the clinical impression. Although serologic studies were performed on a relatively small number of patients, it is reassuring that confirmation of the clinical diagnosis was obtained in a high proportion (84 per cent) of the cases studied in the laboratory. The uniform clinical picture manifested by the majority of patients and the sharp epidemic curve observed in the three schools and in the individual grades of the junior high school are further evidence that a single etiologic agent was responsible for this outbreak.

SUMMARY

During the course of an epidemic of influenza B infection reported in 1945 from many areas in and outside the United States, a sharp outbreak occurred in Needham, Massachusetts. An epidemiologic

and laboratory investigation was carried out in an elementary school and in the junior and senior high schools.

From December 2 to 21 a total of 484 cases of influenza occurred in the three schools, the attack rate per 100 pupils being 53.7 in the junior high, 44 in the elementary school and 24.4 in the senior high school. The distribution of cases by day of onset indicated a sharp epidemic curve in each of the three schools and in the individual grades of the junior high school. The day of highest incidence in the junior high school preceded that in the senior high and Avery schools by a week.

The attack rates in individual classrooms in the junior high school varied from 38.5 to 82.9 per cent. In seventeen classrooms in the junior high school the attack rate was 50 per cent or higher in nine and less than 40 per cent in only three.

Comparison of total absenteeism with that due to influenza during the course of the outbreak revealed marked differences among the three schools. In the junior high school, where the attack rate was highest, influenza was responsible for the greater part of the total school absenteeism. In the remaining two schools many children absent from school did not have influenza. The reliability of absenteeism as an index of the incidence of influenza is at times open to question.

Two strains of virus were readily isolated from cases in Boston, and a third strain was isolated from one of the Needham cases. These three epidemic strains were identified as influenza B viruses.

Of 19 typical cases of clinical influenza in Needham, serologic evidence of influenza B infection was obtained in 16. All asymptomatic contacts failed to show a rise in titer of antibodies for the influenza A and B viruses.

The confirmatory laboratory evidence, the uniform clinical picture manifested by the majority of patients and the sharp epidemic curves noted in all three schools suggest that a single etiologic agent was responsible for this outbreak.

We are indebted to the following officials of Needham for their assistance and for making this study possible: Berwood A. Newman, Superintendent of Schools, Robert McClellan, Health Officer, Rose M. Mayers, R.N., Board of Health Nurse, and Marion Maxwell, R.N. School Nurse.

children a year rose in 1945 to 48. The mothers of 34 of these children gave a history of rubella in pregnancy.²¹ Seventeen per cent of the deaf children in this school had murmurs suggesting congenital heart lesions. Swan and Tostevin²² recently added 40 more cases of rubella during pregnancy to the two earlier series already studied by them. Of these 40 pregnancies, 37 resulted in malformed infants. In the same communication the authors reviewed 16 other pregnancies marked by measles, mumps, rubeola, herpes zoster or scarlet fever. In contrast to the overwhelming evidence of a relation between rubella and malformations, pregnancies associated with the other infections resulted somewhat equivocally. The numerical factors are, of course, such as to make the data on so few cases of limited value. Swan and Tostevin have made the reassuring observations that pregnancies beginning as early as two weeks after maternal rubella are apparently without fetal danger, and that those subsequent to the one complicated by rubella will also result in normal infants.

Among several American reports new and useful approaches to the problem have begun to appear. Cordes and Barber²³ describe the retarded lens development and differentiation of the eye of an embryo removed at the seventh or eighth week from a woman who had rubella a week before artificial termination of pregnancy. Fox and Bortin²⁴ and Aycock and Ingalls²⁵ have begun the essential task of tracing every infant whose mother is known to have had rubella during pregnancy. Their combined results, summarized in the most helpful review by the latter authors,²⁵ give a total of 11 women who developed German measles during the critical first trimester of pregnancy. Eight of the resultant infants were normal, whereas the other 3 were malformed, although in no case did the anomaly affect the eyes or the heart. This group, indicating a hazard of about 25 per cent to the fetus, is too small to allow more than the implication that the fetus can escape involvement.

Several agencies, among them the Massachusetts Department of Public Health²⁷ and a committee representing various national pediatric societies, with Dr. Herbert Miller as chairman, have begun studies by questionnaire to reach a more definite answer to the problem. Co-operation, which of course includes reporting of negative as well as positive results, is strongly urged on all physicians of whom inquiries will be made. Obviously, to know the fetal outcome in a large group of pregnancies associated with definite rubella will be of much greater value than knowledge of how many mothers of malformed infants had rubella during pregnancy. Under present knowledge and until such data are available, a physician whose patient develops definite rubella during the first trimester of pregnancy is forced to consider most seriously the artificial termination of the pregnancy. There are

as yet insufficient data to suggest a like procedure when other infectious diseases occur in early pregnancy.

PREVENTION OF INFECTIOUS DISEASE

Desirability of Exposure to Certain Contagious Diseases in Childhood

During the past few years the philosophy toward the common contagious diseases has markedly changed. Formerly, the appearance of cases of any of the communicable diseases in a group of children resulted in the application of strict quarantine measures to all the contacts. In actual practice such rigid quarantine was rarely successful in localizing an outbreak, but there are stronger reasons for a change in the practice. In the first place, the only protection against these illnesses, which practically everyone must have once in his lifetime, is the immunity that develops as a result of an attack. Secondly, these ailments, like most other infectious diseases, are apt to be much milder in childhood and increasingly serious as the age of the victim increases. Thirdly, the time lost from productive occupation is shorter in childhood and can be better spared. Finally, if the diseases are allowed to remain endemic in the community, devastating and widespread epidemics are prevented.

German measles and mumps provide the strongest argument in favor of childhood exposure. The severity of mumps in adult life, with the frequency of involvement of the gonads, pancreas and central nervous system, is much greater than that in childhood. Although sterility results from bilateral involvement of the testes in the male less often than is customarily supposed,²⁸ it may occur. Both diseases, notably rubella, have been incriminated as a cause of congenital defects in babies born to mothers who escaped the infections in childhood, only to develop them during the first trimester of pregnancy.¹⁵⁻²⁷

Thus, rather than attempt to prevent the spread of chicken pox, measles, German measles and mumps, physicians should encourage them to spread among healthy children. On the other hand, the physician must make it his responsibility to protect patients in whom one of these diseases might have serious consequences. This includes sick or debilitated children, pregnant women, susceptible men who for business reasons cannot afford to be ill and children under three years of age, in whom these diseases may be serious. The importance of assuming this responsibility if one adopts a *laissez faire* attitude in dealing with communicable disease in children is illustrated by a recently reported experience.²⁹ In a private school with an outbreak of mumps it was decided to allow the epidemic to run its course rather than to quarantine all susceptible contacts of the first case. The disease spread as anticipated among the children,

Consequently, the skill in pediatrics of the general practitioner must be adequate so he can play this essential role in child health particularly in the home

This review is written primarily for those general practitioners whose all-important work includes the care of infants and children. We have chosen to stress the preventive side of pediatrics because it occupies such a large part of the efforts of physicians engaged in pediatric practice. Certain fields, in which recent advances have been little short of miraculous, such as the surgical correction of congenital anomalies of the gastrointestinal tract or cardiovascular system, should be mentioned, but have merited separate reports.⁶⁻⁸ The availability of methods for the repair of these congenital defects places an additional burden of responsibility on the general practitioner for their early recognition. Of even greater interest is the accumulation of knowledge concerning the pathogenesis of these defects, since it points the way toward their prevention. This will be apparent in the following sections.

PRENATAL PEDIATRICS

Information related to the nonhereditary processes affecting the child in utero is still largely in the speculative stage. Exact details have not been explored, except in the matter of maternal and fetal blood incompatibilities, which will be the subject of another report.⁹ Progress in a few other matters of prenatal influence is briefly discussed below.

It has been clearly shown by Miller et al.¹⁰⁻¹² and by others¹³ that the infants of women who are, or who later become, diabetic present a collection of anatomic peculiarities acquired before birth. In association with these abnormalities the fetal and neonatal mortality is about 20 per cent, or six times the expected rate for normal pregnancies. This mortality is no less in pregnancies five years before the onset of the mother's diabetes than it is once diabetes has made its clinical appearance. Even ten to twenty years before this event, the fetal and neonatal loss is about three times that expected in women who do not later become diabetic. The fetuses and infants show one or several of the following characteristics: increased birth weight, cardiac enlargement, extramedullary hematopoiesis, hyperplasia of pancreatic islets and a tendency toward gross, nonspecific congenital anomalies.

A connection between this perversion of prenatal development and actual or potential maternal diabetes is obviously present, but its mechanism is completely unknown. Certainly, it has nothing to do with maternal hyperglycemia. Miller¹² lists certain reasons suggesting that the primary derangement is one of maternal anterior pituitary secretion. Whatever the explanation, it is apparent that normal women giving birth to infants weighing 9 pounds or more, or to those with unexplained cardiac hypertrophy or with unexplained features suggesting erythroblastosis, should be followed for

the later development of diabetes mellitus. Finally, of course, the live-born infant with any of these features should be watched with extraordinary care, since only symptomatic means are available for meeting a definite threat to survival.

The relation of maternal nutrition to the proper development and growth of the fetus has been demonstrated by numerous animal and human studies. Warkany's¹⁴ excellent review of these contributions — many of them his own — leaves little doubt that maldevelopment of the animal fetus may be thus brought about. Whether a large number of human congenital abnormalities have this factor as their basis is a problem not yet solved. Warkany's own experimental production of ocular maldevelopment by a maternal diet sharply limited in vitamin A has been confirmed locally in the past year.¹⁵ Food conditions associated with the recent war might be expected to produce deflection of human fetal growth and development. Butler and his associates¹¹ were unable to demonstrate any harm to infants born to ill nourished women who had been interned by the Japanese in the Philippines, but the number of their cases was relatively small. A larger group was studied in Holland, where marked general undernutrition of the urban populace occurred during the winter of 1944-1945.¹⁷ A significant increase in the frequency of congenital malformations was not discovered, although the deprivation was stringent enough to reduce the birth weights and birth lengths of infants born during the hunger months. A most striking feature of the Dutch situation was the development of amenorrhea in at least 50 per cent of women, so that the birth rate at corresponding later dates fell to below half the normal. The sharp decrease in births interfered with statistical evaluation of the importance of the small increase in malformations discovered. Perhaps, as Warkany¹⁴ has said, "the most serious malformation that can befall an infant may be never to be conceived at all."

Although the prenatal influence of maternal diet on fetal growth is an actuality, rather delicately balanced circumstances may be necessary for the potential deflection of fetal development in human subjects. Maternal diets both sufficient to allow conception and deficient enough to interfere with fetal development must fall in a rather narrow band of the nutritional spectrum. Long-continued depletion of the mother, as by improper nutrition for months or years before pregnancy, is likelier to be required than dietary deficiency merely during the pregnancy.

Interest and data concerning maternal infection during pregnancy as a cause of ocular, cardiac, auditory, cerebral and dental maldevelopments are accumulating.¹⁸⁻²³ Reports continue to appear from Australia concerning the effects of maternal rubella in the early part of pregnancy.²⁴⁻²⁶ At a school for the deaf in Brisbane the average admission rate of 7

Immunization of children against both diphtheria and tetanus can be carried out with combined toxoid with good results and few reactions.³⁵ Adolescents and adults are much less liable to severe reactions to tetanus than to diphtheria toxoid, which is fortunate since the immunized person should receive a booster dose of 0.5 to 1.0 cc of tetanus toxoid if he sustains a severe injury that is likely to lead to tetanus. Primary immunization with combined toxoid should be given at the age of six months. Fluid toxoid requires three doses spaced at intervals of two to four weeks, and alum-precipitated toxoid two doses spaced at an interval of two to four months. A disadvantage of the latter is the occasional development of sterile abscesses and the somewhat greater frequency of sensitization to certain components of the toxoid due to the marked adjuvant effect of alum on sensitization. A booster dose of 0.5 cc of the combined toxoids should certainly be given at the age of five years when school starts and perhaps at two years as well, owing to the increased prevalence of diphtheria.^{30, 36}

Vaccination against pertussis is effective in diminishing the incidence and severity of the disease provided an adequate dose of properly prepared Phase I vaccine is used.³⁷ If reactions to pertussis vaccine were not relatively frequent and occasionally severe, there would be no hesitation in recommending its universal administration in infancy. The hazard of the disease is principally in the first year of life, and if, as Sauer³⁸ maintains, immunization should not be started before the age of six months, immunity will not be established until the age of nine or ten months. Recent studies, however, suggest that early immunization can establish adequate antibody levels if alum-precipitated vaccine is used.^{39, 40} If infants are kept at home during the first year, they will not often be exposed without the knowledge of the parents or physician. The administration of hyperimmune human serum,⁴¹ hyperimmune rabbit serum⁴² or concentrated human hyperimmune globulin⁴³ in adequate doses to exposed infants should give passive protection and will usually ameliorate the disease if it develops.⁴⁴ The introduction of streptomycin affords another potential method of treating the disease. In view of all these facts, the use of pertussis vaccine as a routine procedure is somewhat less urgent than formerly but should be encouraged whenever there is a real risk of exposure, particularly in infants in families with a number of older children in school, since pertussis is a serious disease in infancy. In children who have been immunized to pertussis and who are exposed to the disease after six months or more a booster dose of 1.0 cc subcutaneously is recommended. With the general use of pertussis immunization, school quarantine measures should be eliminated,*

since many immunized children escape infection or have unrecognized mild attacks of the disease.

There has been a steady increase in the practice of using combined antigens for routine inoculations.⁴⁵ Combined diphtheria and tetanus toxoid has much to recommend it. Combinations of these two toxoids with pertussis vaccine, either in a fluid state or absorbed on aluminum hydroxide, are available. The advantage of these triple combinations lies in the reduction of the number of injections. When alum precipitation was used with pertussis vaccine, the reaction rate appeared to be increased, but there is insufficient published evidence for an evaluation of the newer aluminum hydroxide preparations.⁴⁶ One reason to question the general use of these triple combined vaccines is psychologic. Immunization with the two toxoids is essential. Reactions are chiefly due to the pertussis vaccine, and with triple vaccines, the occurrence of severe reactions may discourage completion of the course of immunization and discredit the diphtheria toxoid that every child must have.

There are no other vaccines that should be given serious consideration for routine use in children in New England. Influenza A and B vaccine has been proved to diminish the attack rate of epidemic influenza in outbreaks due to both A and B types of virus.^{47, 48} Its use in children, however, seems hardly worth while. Influenza, like other infectious diseases, is milder in childhood than in adult life. Since the duration of immunity from vaccination is probably short, reactions to the various types of vaccines are often considerable and the development of hypersensitivity to egg protein is a possibility, there is something to be said for permitting children to acquire a basic immunity by natural infection with the virus, which may afford some degree of protection to the inevitable exposures in later life.

Scarlet-fever immunization has enjoyed a varying vogue. Since protection is produced only against the toxin and not against infection with the hemolytic streptococcus its value to the child is open to question. Moreover, reactions with the standard plan of toxin injections are often considerable and even dangerous. Since severe, toxic scarlet fever rarely occurs today and penicillin therapy adequately controls the septic aspects of streptococcal infection, there is little justification for immunization at present. The intradermal injection of a tannic acid precipitated toxin may obviate some of the objections to scarlet-fever immunization.⁴⁹

The question of immunization against typhoid fever, typhus, cholera, plague and yellow fever may arise in children going overseas to join their families in Europe and Asia. It should be emphasized that, with these diseases, immunization is only one of the important measures necessary to prevent the infection. Since the food of the infant can be sterilized by an intelligent mother, there appears to be little need for cholera or typhoid injections before six

*Families, however, should be notified of the presence of pertussis or other contagious diseases in the school so as to permit the protection of vulnerable persons, such as newborn babies by isolation or passive immunization.

but unfortunately a number of cases of severe mumps, including several of orchitis and meningo-encephalitis, resulted when the virus was carried to nonimmune parents by the children. It should also be stressed that, although quarantine of contacts is not recommended in the group of diseases mentioned, such an attitude cannot be adopted with diphtheria because of its serious consequences.

Immunization

The efficacy of active immunization has been conclusively demonstrated in diphtheria, tetanus and smallpox. Vaccination methods have also been developed for a number of other diseases, against which active immunization appears to have a definite but less clear-cut effect. In many cases—for example typhoid fever and typhus—it is difficult to apportion the credit for control of epidemics between immunization and effective sanitation.

Routine immunization is the responsibility of every physician who takes care of children. A recent progress report³⁰ presented an exhaustive review of the field of active immunization, so that this report is confined to an attempt to answer the following practical questions:

- Against what diseases should children in New England be immunized?
- When should immunization be carried out?
- What types of preparation should be used?
- How often should reinoculation be performed?
- What dangers are there in immunization?

Our attempt to answer these questions may appear dogmatic. This is not the intention. There are a number of methods for achieving the same objective, and the factors in each case should be weighed. For example, smallpox vaccination should be the initial immunization procedure in any community where the disease has recently been reported, whereas it can ordinarily be deferred until tetanus inoculations have been given. The essence of good medical practice is flexibility based on an understanding of basic principles.

Vaccination against smallpox is absolutely essential. Cases of the disease continue to occur in the United States, and the freedom from epidemics is mainly due to nearly universal vaccination. It should be performed in the first year, since the incidence of its chief complication, postvaccinal encephalitis, is considerably higher in persons whose initial vaccination is performed in childhood or adult life.³¹ Since tetanus has followed vaccination, particularly when tight shields were used,³² vaccination after the completion of tetanus immunization is sometimes preferred. The principal causes of failure to obtain a reaction is a lack of appreciation that the vaccine is a living virus, which may be inactivated by improper or prolonged storage or by

the use of alcohol, iodine or mercurial antiseptics to cleanse the skin. Only a volatile substance such as ether or acetone should be used, and this should be allowed to evaporate before the skin is pricked. All the lymph in the tube should be squeezed on the skin, because the lymph may separate from the glycerin. Revaccination should be carried out routinely when the child first goes to school, again at the age of eighteen and when there is an outbreak of the disease or the person is going to a foreign country. In revaccination the physician should not be satisfied with a negative reaction but should insist on an immune, modified or typical response.

Diphtheria is one of the most serious preventable health hazards to children in New England, and hence immunization should be given as early as practicable. The original idea that one could not obtain a satisfactory immunity by inoculations given to infants under six months of age is now undergoing close scrutiny, but it is too early to recommend change of the standard procedure of beginning diphtheria immunization at the age of six months. Formerly, most newborn infants were found to be Schick negative as a result of the passive transfer of maternal antitoxin. Now, however, there is a considerable percentage of Schick-positive persons in the adult population, and their infants will be born without such an immunity. This raises the question of early immunization of the infant or of prenatal immunization of the mother.³³ Unfortunately, adults frequently have severe local and constitutional reactions to diphtheria toxoid, so that immunization of the mother should not be considered until the latter half of pregnancy, when damage to the fetus by a reaction is no longer a real possibility. Until a more satisfactory method for immunization of adults against diphtheria is worked out, physicians should probably adopt the attitude of being alert to diagnose diphtheria infection and of beginning immunization promptly at the age of five or six months. If an infant is exposed to diphtheria, antitoxin should not be given unless clinical diphtheria develops. The choice of agents and times for booster doses of diphtheria toxoid is discussed below under tetanus immunization.

Tetanus immunization should be a routine procedure in childhood for the following reasons: it is an infrequent but dangerous disease, although it rarely occurs in adults except after serious injuries; a large proportion of cases in childhood follow injuries and infections so mild that the patients are unlikely to seek medical advice³⁴; the use of tetanus antitoxin may sensitize the patient to horse serum, making it difficult to administer diphtheria antitoxin subsequently, and if the patient has been immunized against tetanus, the physician is spared the frequently difficult decision regarding the advisability of administering tetanus antitoxin for many of the minor cuts and injuries in childhood.

bacterial respiratory infections. It is possible to diminish the bacterial content of air by the use of ultraviolet irradiation,⁶² by the vaporization of glycols⁶³ and by treating floors and bedding with oil to make bacteria and dust adhere.⁶⁴ Nevertheless, the rigid observance of strict isolation technic is an absolute necessity in the care of sick infants in a hospital, if the number of cross infections is to be reduced. Children with diarrhea, draining ears, acute respiratory infections and skin infections (impetigo or eczema) should be rigidly isolated in single rooms whenever possible.

(To be concluded)

months of age. So far as plague and typhus are concerned, however, it is equally essential for the mother to know the endemic status of the disease in her area and to make sure that nursemaids, cooks and so forth are not carriers of the insect vectors involved. In general, the vaccines against typhoid fever, plague, cholera and typhus may be given to children by the same schedule as that for adults, half the adult dosage being used for children under five years of age. It should be remembered that

TABLE 1 *Mortality among Patients Contracting Tuberculosis in Childhood*

stimulating doses must be given every six months for typhus and every four months for cholera and plague, and that immunization should be completed two weeks before the subject enters an endemic area.⁵⁰ The chance of exposure of infants to yellow fever is slight in urban areas, but immunization should probably be given when it is recommended by local health authorities, since lasting protection is thereby afforded.

The use of immune serum globulin in the prophylaxis of measles in exposed persons has become an established pediatric procedure. A dose of 0.1 cc per pound of body weight will prevent the disease in the great majority of cases, whereas 0.02 cc per pound of body weight will usually allow the patient to experience a modified attack. The globulin is given intramuscularly and should be administered in the first six days after exposure. The larger preventive dose should be used for children under three years of age or for sick, debilitated and tuberculous children, and modification should be attempted in all other healthy children who have been exposed to the disease. Modified measles, which is less severe and less apt to be followed by complications, probably gives relatively permanent immunity to most children.⁵¹

The prophylactic administration of chemotherapeutic drugs has a limited but definite place in preventive medicine. Certain groups of children — notably those who have had one or more attacks of rheumatic fever — run a serious risk of recurrence with an increase in cardiac damage if they contract an infection with Group A beta-hemolytic streptococci.⁵² Once they have recovered from their original attack of rheumatic fever, there are psychologic objections to removing these children from their normal environment. Since their homes or schools seldom experience a winter without the occurrence

of hemolytic streptococcus infection in some member of the group, there is a special risk for these children at home and at school. The use of prophylactic sulfadiazine — in doses of 0.25 gm twice a day to young children and of 0.5 gm twice a day to older children and adolescents — throughout the danger season (from October to June) has seemed to be helpful in diminishing the incidence of rheumatic recurrence.⁵³ The children should be carefully observed for rash or granulocytopenia particularly during the first six to eight weeks, when most of these reactions occur. If sulfadiazine-resistant organisms become more prevalent, this chemoprophylaxis will obviously be less effective, and studies with the use of oral penicillin will be necessary. At the moment its routine use for this purpose cannot be recommended and would be financially burdensome. Unfortunately, the penicillin treatment of established streptococcal infections has not seemed to prevent rheumatic fever or its recurrences or to affect the course of the disease once it has developed.^{54, 55}

Children with rheumatic heart disease or with congenital heart lesions, particularly patent ductus arteriosus or patent interventricular septum, should be given penicillin treatment whenever dental extractions or tonsillectomies are performed, in the hope that the development of subacute bacterial endocarditis will be prevented.⁵⁶ Ideally, treatment with full doses should be begun forty-eight hours before operation and continued for five days afterward. The responsibility of keeping the teeth of these patients in good condition is particularly great for the same reason.

The family physician is the person who can do most to control tuberculosis in childhood. The serious prognosis of primary tuberculosis in infancy is indicated in Table 1. The suspicion of tuberculosis in any adult in a home with children should immediately be followed up with x-ray examination. Now that milk is no longer a serious source of infection, tuberculosis in infants and children is almost invariably the result of household contact with an adult who is spreading tubercle bacilli.⁶⁰ The only way to prevent tuberculosis is to find all persons with positive sputums and remove them from contact with children. With the Vollmer patch test,⁶¹ tuberculin testing can be carried out routinely in children at intervals of a year, starting at six months of age. The emphasis, however, should be on the discovery of the adult who is the source of the infection, *before* the children become infected rather than afterward.

No discussion of the prevention of infectious disease in children would be complete without mention of the fact that hospitals remain discouragingly dangerous places for infants and children. Transmission of virulent bacteria from one child to another and from attendants takes place all too frequently. Epidemic diarrhea has proved to be even more readily communicable than the ordinary

and the QRS complex in Lead 3 was W-shaped. The T waves were upright in Leads 1 and 3 and slightly low in Lead 2, the ST segment in Lead CF₁ was slightly sagging, and the T wave was diphasic.

Three months before entry there was a marked increase in the substernal discomfort. Attacks of steady, crushing substernal pain radiating down both arms into the back and up the neck to the jaw were brought on by slight exertion, occurring about once a day and lasting about fifteen minutes at a time. A month later the patient developed a cough that was productive of white mucoid sputum and was particularly severe at night. A month before entry he was forced to stop working. The attacks had begun to occur even while he was resting, and he sometimes awoke with the sensation in the morning. The pain was so severe that he always had to stop whatever he was doing until it had subsided. At the time of entry he was having as many as four attacks a day and was practically bedridden. Mannoitol hexamitrate was of no avail. Nitroglycerin gave some relief but was followed in several hours by nausea and vomiting.

Physical examination disclosed an anxious patient who was repeatedly belching small quantities of air. The left fundus showed an occlusion of the superior temporal artery just off the disk, as evidenced by parallel ensheathing of the arterial walls for a distance of 1 or 2 disk diameters. Otherwise the vascular changes appeared if anything less severe than those on the first examination. The left border of the heart was in the anterior axillary line in the fifth and sixth interspaces. The aortic second sound was much louder than the pulmonic second. There was a questionable apical gallop. The lungs and abdomen were clear.

Examination of the blood showed a red-cell count of 5,310,000, with 15.0 gm of hemoglobin, and a white-cell count of 9200, with 80 per cent neutrophils. The urine had a specific gravity of 1.020 and gave a ++ test for albumin.

An electrocardiogram showed a sinus rhythm at a rate of 90 per minute. The S waves were sagging in Leads 1 and 2, and the T waves were sagging, low and diphasic in Leads 1 and 2, upright in Lead 3 and inverted in Lead CF₁, the ST segment was sagging in Lead CF₁.

On the second hospital day, during a bed bath, the patient suddenly complained of dizziness and lapsed into unconsciousness. When a physician arrived two minutes later the heart had ceased beating, and the patient was somewhat cyanotic. He emitted several gasps during the following three minutes. Despite the intracardiac administration of coramine the heart action could not be re-established.

DIFFERENTIAL DIAGNOSIS

Dr. EDWARD F. BLAND. This is in some respects a discouraging case but an important one. The pa-

tient died at twenty-seven years of age. At the age of twenty-three he had, by most criteria, malignant hypertension—at least, it was acute and severe, and there was beginning retinitis and choking of the optic disks. Renal function was somewhat impaired, although the concentrating power of the kidneys was good. If a patient with this situation appeared again tomorrow, we should consider him a candidate for an almost emergency sympathectomy. There may be some dissenting voices, however, on that score.

In looking back over the record, we are most interested in the evidence whether or not sympathectomy had any effect on this patient's subsequent course. The chief complaint on the first admission was headache, he was largely relieved of this symptom. It has been noted in many cases after sympathectomy, even though the high blood pressure in some cases has been only slightly or moderately ameliorated, that the relief of troublesome headaches has been striking. Furthermore, it is of special interest that four years later the renal function actually seemed a trifle better and the eye grounds were no worse, some observers even thought that they were better. In other words, it seems as though the sympathectomy, without influencing significantly the level of the blood pressure, had in some fashion protected both the eyes and the kidneys. A final point—if we can consider this clinically malignant hypertension, without necrotizing renal arteriolitis by biopsy—is that a twenty-three-year-old patient would have been expected to succumb in a few years in uremia. He died four years later, but not in uremia.

Is there anything that we need say about the differential diagnosis? In any person of this age with hypertension one should consider coarctation of the aorta, but presumably he did not have that. Nothing is said about the arterial pulsations in the legs or notching of the ribs on x-ray study, but almost certainly if abnormal these would have been mentioned. A condition that might be considered in passing is a paraganglioma. The hypertension was not paroxysmal, but we know that perhaps 10 per cent of patients who have hypertension secondary to paraganglioma have sustained hypertension. If such a lesion had been present it would probably have been discovered at operation, since it is routine to search carefully for these tumors, they are not always found in the immediate vicinity of the kidney, however. We are not told the reaction of his blood pressure to change in posture. Dr. Smithwick* has recently pointed out that if the hypertension is due to a tumor of this type the blood pressure falls in a striking fashion when the patient shifts from a recumbent to a standing position. He has studied only a few cases, but that seems to be the pattern. In the case under discussion we have no reason to think that the hypertension was secondary to tumor.

CASE 33231

PRESENTATION OF CASE

First admission A twenty-three-year-old machinist entered the hospital two months after he had been rejected by his Selective Service board because of hypertension.

The patient had been in perfect health until a year before entry, when he began to have a "tired feeling" and discomfort in the low back, which he attributed to overwork and long hours of standing, it occurred about once in three or four weeks and was relieved by rest. At the same time frontal headaches also developed, occurring about once a week and lasting four or five hours. Six months before entry he first noticed easy fatigability.

The patient was in good physical condition but appeared apprehensive. The fundi showed borderline blurring of the disks and diffuse narrowing of all the retinal arteries, there was little arteriovenous nicking. The diastolic blood pressure in the retinal arteries was 65. There was a loud, snapping aortic second sound, and a blowing apical systolic murmur, which was not transmitted. The pulse was bounding. Examination of the lungs and abdomen was negative.

The temperature, pulse and respirations were normal. The blood pressure was 245 systolic, 160 diastolic.

Examination of the blood showed a hemoglobin of 87 per cent and a white-cell count of 11,250. The nonprotein nitrogen was 38 mg., and the cholesterol 170 mg. per 100 cc. A blood Hinton test was negative. The urine gave a ++ test for albumin, but the sediment did not contain cells or casts. A phenolsulfonephthalein test showed 51 per cent excretion of the dye in 2 hours. The maximum specific gravity in the urinary concentration test was 1.018.

X-ray films of the chest showed a cardiothoracic ratio of 12.5:28.5. The left ventricular area was somewhat blunted, and the aortic knob slightly more prominent than normal. An intravenous pyelogram showed little dye excretion on the right, this was repeated and confirmed. The left kidney appeared normal. There were some calcified pelvic arteries. A retrograde pyelogram was normal.

An electrocardiogram showed a normal rhythm, a rate of 85 per minute and a PR interval of 0.16 second. The T waves were inverted in Lead 3, low and notched in Lead 4 and low in Lead 1. A sedation test reduced the blood pressure to 150 systolic, 110 diastolic.

A left lumbar sympathectomy was performed with removal of the sympathetic trunks from the fifth dorsal to the second lumbar segment inclusive. Following the operation the patient developed a serosanguineous effusion in the left side of the chest but recovered satisfactorily and was discharged on the forty-first hospital day.

Second admission (three weeks later) The patient was readmitted for a right lumbar sympathectomy.

At operation the right kidney was found to be grossly normal, but a biopsy was reported as showing nephrosclerosis, Grade III. At discharge the blood pressure while the patient was standing was 165 systolic, 110 diastolic.

Final admission (four years later) The patient was followed in the Out Patient Department. Six months after discharge the blood pressure had returned to 230 systolic, 140 diastolic. He felt well, however, and the headaches had almost disappeared. Eight months after discharge he returned to work. Two years before entry the main complaints were lack of libido and insomnia. He worked eight hours a day and experienced fatigue only after particularly great effort. The blood pressure when the patient was lying down was 240 systolic, 135 diastolic. The insomnia was finally controlled with phenobarbital. Potassium thiocyanate was used to treat the hypertension but was discontinued by the patient because of postprandial pains across the chest and down the left arm to the elbow. A year and a half before entry he began to have episodes of precordial "squeezing" sensations, occasionally radiating down both arms and occurring several times a month when he was walking or climbing stairs or after eating. After a few minutes of rest the feeling disappeared. The blood pressure at that time was 270 systolic, 170 diastolic, and he was occasionally found to have a gallop rhythm. His working time had been reduced to six hours. Five months before entry a chest film showed a cardiothoracic ratio of 14:29, as well as some prominence in the region of the left ventricle.

The lung fields were clear except for some blunting of the right costophrenic angle. An intravenous pyelogram showed prompt excretion of dye on both sides. A phenolsulfonephthalein test showed 63 per cent excretion of the dye in 2 hours. The urine had a specific gravity of 1.020 and was free of albumin. The nonprotein nitrogen was normal. An electrocardiogram showed a sinus rhythm and a rate of 90. The PR interval was 0.17 second, and the QRS complex 0.08. The axis and voltage were normal. There was prominence of the ST segment in Lead 2,

thectomy might be given credit for having exerted a protective action on the kidneys, because the patient did not develop progressive renal failure. It is true that death in uremia with the post-mortem finding of necrotizing renal arteriolitis is the expected end-result in patients who conform to Fahr's original criteria for the diagnosis of malignant hypertension, but this unfortunate term has been redefined in so many different ways during the past twenty years that there are now no generally accepted minimum criteria for a clinical diagnosis of malignant hypertension. In this case, the diagnosis seems to have been based mainly on the patient's age and the finding of "questionable blurring of the optic disks." Even if the diagnosis of malignant hypertension is accepted, however, it does not seem justifiable to assume that the untreated course would inevitably have led to progressive renal failure, and therefore to suggest that sympathectomy exerted a protective action on the kidneys because renal failure did not occur. On the contrary, it seems to me that there is nothing in the history of this case that is incompatible with the assumption that the operation had no significant beneficial effect on the progress of the disease, which ran a fairly rapid course from accidental discovery to death in a period of four years.

In conclusion, I should like to make it clear that my remarks are not intended to convey the impression that sympathectomy should not have been performed on this patient, or that it should not be given a trial in other cases of a similar nature. On the contrary, the shortcomings of other methods of treatment are so obvious that it seems perfectly reasonable to proceed with the operation, merely because one can offer little else that may be expected to exert a beneficial effect on the course of the disease. I believe, however, that we can hope to arrive at an accurate evaluation of the real therapeutic effectiveness of sympathectomy in the treatment of hypertension only if we analyze the results in each case with the maximum degree of objectivity.

CLINICAL DIAGNOSES

Malignant essential hypertension
Hypertensive heart disease
Cardiac arrest

DR. BLAND'S DIAGNOSES

Essential hypertension, severe
Hypertensive and coronary heart disease
Angina pectoris decubitus
Lumbodorsal sympathectomy

ANATOMICAL DIAGNOSES

Arteriosclerosis, coronary, severe, with extreme narrowing
Cardiac hypertrophy and dilatation, slight
Myocardial infarcts, focal, old and recent

Arteriolar nephrosclerosis, severe right, minimal left
Arterial and arteriolar sclerosis, generalized, moderate

Operations: bilateral lumbodorsal sympathectomy, old

PATHOLOGICAL DISCUSSION

DR. MALLORY: Interest naturally centers on the histologic findings in the kidneys. At the time of the sympathectomy, biopsies were done on both kidneys. It will be recalled that the right kidney had shown possible evidence of impaired function, if the intravenous pyelogram is to be credited. Later, however, the dye excretion improved on that side. The biopsy of the right kidney showed quite marked arteriolar changes, which we classified as Grade III, whereas the biopsy from the left kidney showed only Grade I changes. At autopsy the same degree of difference was apparent on the two sides, although there was progression of both. Even the more severely involved kidney showed no necrotizing arteriolitis.

The other findings were approximately as expected. The heart showed moderate hypertrophy, weighing 430 gm. The major coronary arteries were severely sclerotic, and the lumens reduced to pin points—in some places there was no lumen. There was no major infarction of the heart, but the myocardium presented evidence of some focal old scarring and also evidence of numerous small spots of fresh necrosis of cardiac muscle that had the appearance of being two to four days old. This fresh necrosis coincided with the period of terminal entry to the hospital. The lungs showed chronic passive congestion.

CASE 33232

PRESENTATION OF CASE

A forty-nine-year-old man entered the hospital because of retrosternal and epigastric pain.

Three and a half hours before admission, during a heated argument, the patient was suddenly seized by a pain in the neck, at about the level of the thyroid cartilage. He was forced to sit down and was unable to talk or breathe properly for about fifteen minutes. During that time the pain gradually traveled downward anteriorly in the midline to the upper abdomen and finally settled in the left upper quadrant, radiating through the body to the angle of the left scapula. It remained constant in the retrosternal and abdominal location, until the time of admission. No nausea, vomiting, hemoptysis or other symptoms accompanied this attack. Three days prior to admission the patient had slipped and fallen on a curbstone, with considerable resulting pain and ecchymoses and swelling of the left leg. In addition, for ten days he had had a slight cough productive of whitish sputum in which there were occasional small amounts of blood.

The final condition that we might consider is primary renal disease on the basis of pyelonephritis in the past, with renal injury. We have no real evidence to suggest this. The retrograde pyelograms showed no irregularity in contour of the ureters, pelves and calyces, and there was no indication of chronic renal infection. Therefore, we must dismiss these other possibilities and say that this was a case of essential hypertension occurring acutely and severely in a relatively young person. He ultimately died of severe angina pectoris on the basis of coronary disease. At the final admission he did not live long enough to have special studies or therapy instituted. I suspect that those in charge were at somewhat of a loss regarding just what therapy to institute. In addition to nitrates and oxygen, he was probably given digitalis, because of the cardiac enlargement and weakness (gallop rhythm). If he had survived long enough it might have been helpful to have him on a rice diet or at least on a low-sodium regime. If he had improved a little on that and yet continued to have intractable angina pectoris, one might have seriously considered a thoracic sympathectomy for relief of pain.

The cause of this patient's sudden exitus was almost certainly cardiac and not cerebral. It was too abrupt for a cerebral accident. The heart was not beating when the physician, who presumably was nearby at the time, arrived a moment later. Perhaps acute coronary insufficiency is as good an explanation clinically as anything else. For a final diagnosis I believe that he had severe essential hypertension, hypertensive and coronary heart disease and angina pectoris decubitus. He ran a progressively downhill course, so far as the hypertension and coronary disease are concerned, and yet I am forced to think that he received some benefit from the sympathectomy regarding protection of the kidneys and eyes and certainly relief from headaches. Whether or not it was worth while in this case is debatable, but I should strongly recommend the same procedure if faced with a similar situation.

DR ROBERT S PALMER Dr Bland has summarized this case extremely well. In young patients like this, with a high diastolic pressure and early papilledema, we have seen the best results from sympathectomy, provided that cardiac and renal functions are seriously impaired. There have been 3 such patients, three to five years after operation, with normal or nearly normal blood pressures. Two other similar patients, who were considered to have malignant hypertension when operated on three and five years ago, are alive and working, although again hypertensive. One is working in a grocery handling heavy goods. Unfortunately, persistent high diastolic pressures are often associated with diffuse arteriolar disease. There was some evidence of this in the case under discussion. I think that this patient was probably relieved, that his

life was prolonged and that the renal function may have been spared. Dr Bland mentioned emergency sympathectomy. Delay may be costly, since renal damage may advance rapidly, seemingly in a matter of days. I think that I have seen the entire course of malignant hypertension from symptomatic onset to death in five or six weeks. Rarely, there may be such a thing as emergency sympathectomy to spare kidney damage.

DR BENJAMIN CASTLEMAN How often have you seen the onset of angina following sympathectomy in patients who have never had it before?

DR PALMER I do not know. This is certainly an outstanding example. I have had the impression that some people with dorsolumbar sympathectomy and resulting postural hypotension have been relieved of angina even when high dorsal sympathectomy was not done, but I cannot speak definitely on this point.

DR WALTER BAUER What right have you to say that sympathectomy will prevent irreversible uremia? There are many other reasons to prevent irreversible kidney lesions.

DR PALMER If I said what Dr Bauer says I did it was a rash statement, and I am glad to be corrected. If the patient is operated on, the operation should be done before serious impairment of renal function sets in. It seems that some of our patients closely similar to this, have continued a long time without progressive kidney change, whereas patients with malignant hypertension who have not had sympathectomy, as Dr Bland has pointed out often have progressive changes in the kidneys and die in uremia. I should point out that it is remarkable for a person with this type of hypertension to have gone so long without more kidney damage. I am not sure, from the qualitative tests of renal function, that positive improvement in renal function was demonstrated.

DR TRACY B MALLORY Dr Evelyn, will you express your views on the subject?

DR KENNETH A EVELYN In this case, as in many similar cases that have been reported in the literature, I find it difficult to accept the evidence brought forward in support of the claim that sympathectomy has a specific ability to relieve headache even in patients in whom the operation fails to produce a significant lowering of the blood pressure. It is well known that relief of symptoms in hypertensive patients may occur after a variety of nonspecific therapeutic measures, including venesection and psychotherapy, but when there has been no reduction of blood pressure it does not seem justifiable to ascribe any specific virtue to sympathectomy in this regard. In any event, in this particular patient, headache was a relatively minor complaint even before the operation.

My second comment concerns the diagnosis of malignant hypertension in this patient and the validity of Dr Bland's suggestion that the sympha-

Six hours after the acute attack, the patient complained of throbbing chest pain, became cyanotic and died.

DIFFERENTIAL DIAGNOSIS

DR OGLESBY PAUL. In brief, this is the case of a forty-nine-year-old hypertensive man with a background of rheumatic heart disease who, after ten days of cough and hemoptysis and with a three-day-old abrasion of the left leg, entered the hospital with severe pain in the neck, chest, back and upper abdomen. Examination was essentially nega-

FIGURE 3

some disease of the leg veins. Prolonged, severe and widespread pain of this type, however, is not characteristic of that condition, and the absence of tachycardia and dyspnea essentially excludes such a diagnosis. In this patient pain was the cardinal symptom, with embolism to the lung, on the other hand, shortness of breath is usually predominant, and there may be no pain at all. Furthermore, definite evidences of a peripheral phlebitis are lacking, and there were no x-ray signs of pulmonary infarction.

Might not this man have had a myocardial infarct? There are several points in the case history that would seem to make such a condition not the diagnosis of choice. In the first place, as has been often pointed out, the pain associated with myocardial infarction does not typically occur abruptly as in this case but may build up with increasing intensity over a matter of minutes or even hours. Next, one notes the absence of arm discomfort and the presence of back and abdominal pain. Coronary occlusion with myocardial infarction certainly may be accompanied by pain in these last two areas, but perhaps such a complaint is more characteristic of a dissecting aneurysm. During the period of hospitalization no helpful findings, such as pericardial friction rub and electrocardiographic evidence of infarction, appeared. Finally, the past history as given contains no mention of angina pectoris or of previous episodes of pain that might have been interpreted as being of coronary origin.

Could the pathologist have given the medical man a surgical abdomen to discuss? If this man had a ruptured viscus, acute pancreatitis or mesenteric thrombosis, he showed an extraordinarily normal abdomen throughout, in addition to a well behaved intestinal tract, which did not even cause nausea or constipation. I cannot make a purely intra-abdominal diagnosis.

It seems that the one condition that fits this man's illness best is a dissecting aneurysm. He belongs to the right age group for such a diagnosis, and at this hospital, we have encountered more men than women with that diagnosis. The presence of significant hypertension is almost an invariable finding, and as with this man, the blood pressure is often sustained at a high level until the last moments of life. The first dissection in the media of the aorta may result in sudden excruciating and prolonged pain, which may be referred to both the thorax (anteriorly and posteriorly) and the abdomen. It is usual for these patients to survive for a matter of hours or days, rarely even for years, and sudden death at the onset is not found in most cases. The essentially negative physical examination is also consistent with such a diagnosis, and the lack of change in the electrocardiogram is an expected finding. Indeed, a changing electrocardiographic pattern would make one think of something other than a dissecting aneurysm.

tive, except for the hypertension and slight left upper-quadrant tenderness, and after a five-day course he succumbed with an exacerbation of symptoms. On reading the history, one is more impressed by the negative findings than by the positive ones. The lungs were never mentioned as having been abnormal on physical examination, the heart, except for enlargement in keeping with the hypertension and rather questionable evidence of mitral stenosis was not remarkable, and the abdomen was notable for its normal character. The laboratory data revealed only a moderate leukocytosis and a terminal clouding of the left lung field on x-ray study, the latter being the only definitely helpful findings. A low-grade fever was present throughout.

Several diagnoses that come to mind should be mentioned for the sake of completeness but appear unlikely. The sudden onset of severe chest pain suggests a spontaneous pneumothorax, but the physical and x-ray findings allow us to rule out such a possibility. Mediastinal emphysema may also be eliminated on the same grounds. Pulmonary embolism is suggested by the history of trauma to one leg, by the sudden onset and by the evidence of

At the age of nine years there had been an attack of rheumatic fever, allegedly with cardiac involvement, which had lasted three months. There were no recurrences. Before his illness, the patient's weight had been normal, afterward, he began to gain and at fourteen years of age weighed 216 pounds.

At the time of admission, the patient was sweating and rolling from side to side with pain. Extreme obesity — the patient weighed 270 pounds — made physical examination difficult. There were bilateral cataracts. The heart and lungs were normal. There was slight tenderness in the left upper quadrant near the costal margin. The abdomen was soft, no organs or masses were palpable. A large contusion covered the anterior surface of the left leg from above the knee to the mid-tibia. There were many superficial varicose veins over both legs.

The temperature was 100°F, the pulse 82, and the respirations 16. The blood pressure was 190 systolic, 120 diastolic.

Examination of the blood revealed a hemoglobin of 16.5 gm per 100 cc and a white-cell count of 10,400, with 83 per cent neutrophils. The urine contained no albumin. In the sediment there were 1 to 3 red cells and an occasional white cell per high-power field. In the x-ray film of the chest, the lungs appeared clear. The heart was enlarged and the aorta tortuous (Fig 1). An electrocardiogram on

FIGURE 1

admission and another five days later showed changes consistent with left-axis deviation, no indication of infarction was observed in either film. Shortly after admission the serum amylase level was 20 units, and the nonprotein nitrogen 23 mg per 100 cc.

On the morning of the second hospital day the general condition appeared improved. Gas and feces were passed freely. Despite morphine and Demerol, the abdominal pain persisted steadily. By evening the temperature had risen to 101°F, remaining between 99.5 and 101° thereafter. By evening the pain had progressed down the abdomen below the umbilicus, while persisting in the former locations. The white-cell count rose to 14,800. Rare white cells, red cells and epithelial cells were present in the urine. A repeat chest film compared to that of the first day showed a generalized increase in the pulmonary vascular markings (Fig 2). A

FIGURE 2

plain film of the abdomen was normal. On the third day no essential change was noted, but occasional extrasystoles with long compensatory pauses were detected. The mitral first sound had a peculiar quality, thought to represent a presystolic murmur, and after some of the extrasystoles there was a mid-diastolic rumble. The pulsations in the dorsalis pedis artery were strong.

No new events occurred until the evening of the fifth day, when the pain became extremely sharp and extended into the epigastrium, up into the neck and back to the epigastrium over a fifteen-minute period. Ten minutes later it again shifted, this time to the sixth intercostal space in the anterior axillary line. The patient was sweating and rolling about in pain. He became cyanotic, pale and cool. The blood pressure fell from 190 systolic, 110 diastolic, at the onset of the episode to 80 systolic, 60 diastolic, at its end, later rising to 120 systolic, 100 diastolic. A chest film showed homogeneous density over nearly the entire left lung field (Fig 3).

Six hours after the acute attack, the patient complained of throbbing chest pain, became cyanotic and died.

DIFFERENTIAL DIAGNOSIS

DR. OGLESBY PAUL. In brief, this is the case of a forty-nine-year-old hypertensive man with a background of rheumatic heart disease who, after ten days of cough and hemoptysis and with a three-year-old abrasion of the left leg, entered the hospital with severe pain in the neck, chest, back and upper abdomen. At the age of nine years there had been an attack of rheumatic fever, allegedly with cardiac involvement, which had lasted three months. There were no recurrences. Before his illness, the patient's weight had been normal, afterward, he began to gain and at fourteen years of age weighed 216 pounds.

At the time of admission, the patient was sweating and rolling from side to side with pain. Extreme obesity — the patient weighed 270 pounds — made physical examination difficult. There were bilateral cataracts. The heart and lungs were normal. There was slight tenderness in the left upper quadrant near the costal margin. The abdomen was soft, no organs or masses were palpable. A large contusion covered the anterior surface of the left leg from above the knee to the mid-tibia. There were many superficial varicose veins over both legs.

The temperature was 100°F, the pulse 82, and the respirations 16. The blood pressure was 190 systolic, 120 diastolic.

Examination of the blood revealed a hemoglobin of 16.5 gm per 100 cc and a white-cell count of 10,400, with 83 per cent neutrophils. The urine contained no albumin. In the sediment there were 1 to 3 red cells and an occasional white cell per high-power field. In the x-ray film of the chest, the lungs appeared clear. The heart was enlarged and the aorta tortuous (Fig 1). An electrocardiogram on

FIGURE 1

admission and another five days later showed changes consistent with left-axis deviation, no indication of infarction was observed in either film. Shortly after admission the serum amylase level was 20 units, and the nonprotein nitrogen 23 mg per 100 cc.

On the morning of the second hospital day the general condition appeared improved. Gas and feces were passed freely. Despite morphine and Demerol, the abdominal pain persisted steadily. By evening the temperature had risen to 101°F, remaining between 99.5 and 101° thereafter. By evening the pain had progressed down the abdomen below the umbilicus, while persisting in the former locations. The white-cell count rose to 14,800. Rare white cells, red cells and epithelial cells were present in the urine. A repeat chest film compared to that of the first day showed a generalized increase in the pulmonary vascular markings (Fig 2). A

FIGURE 2

plain film of the abdomen was normal. On the third day no essential change was noted, but occasional extrasystoles with long compensatory pauses were detected. The mitral first sound had a peculiar quality, thought to represent a presystolic murmur and after some of the extrasystoles there was a mid-diastolic rumble. The pulsations in the dorsalis pedis artery were strong.

No new events occurred until the evening of the fifth day, when the pain became extremely sharp and extended into the epigastrium, up into the neck and back to the epigastrium over a fifteen-minute period. Ten minutes later it again shifted, this time to the sixth intercostal space in the anterior axillary line. The patient was sweating and rolling about in pain. He became cyanotic, pale and cool. The blood pressure fell from 190 systolic, 110 diastolic, at the onset of the episode to 80 systolic, 60 diastolic, at its end, later rising to 120 systolic, 100 diastolic. A chest film showed homogeneous density over nearly the entire left lung field (Fig 3).

Six hours after the acute attack, the patient complained of throbbing chest pain, became cyanotic and died.

DIFFERENTIAL DIAGNOSIS

Dr. OGLESBY PAUL In brief, this is the case of a forty-nine-year-old hypertensive man with a background of rheumatic heart disease who, after ten days of cough and hemoptysis and with a three-day-old abrasion of the left leg, entered the hospital with severe pain in the neck, chest, back and upper abdomen. Examination was essentially nega-

FIGURE 3

tive, except for the hypertension and slight left-upper-quadrant tenderness, and after a five-day course he succumbed with an exacerbation of symptoms. On reading the history, one is more impressed by the negative findings than by the positive ones. The lungs were never mentioned as having been abnormal on physical examination, the heart, except for enlargement in keeping with the hypertension and rather questionable evidence of mitral stenosis was not remarkable, and the abdomen was notable for its normal character. The laboratory data revealed only a moderate leukocytosis and a terminal clouding of the left lung field on x-ray study, the latter being the only definitely helpful findings. A low-grade fever was present throughout.

Several diagnoses that come to mind should be mentioned for the sake of completeness but appear unlikely. The sudden onset of severe chest pain suggests a spontaneous pneumothorax, but the physical and x-ray findings allow us to rule out such a possibility. Mediastinal emphysema may also be eliminated on the same grounds. Pulmonary embolism is suggested by the history of trauma to one leg, by the sudden onset and by the evidence of

some disease of the leg veins. Prolonged, severe and widespread pain of this type, however, is not characteristic of that condition, and the absence of tachycardia and dyspnea essentially excludes such a diagnosis. In this patient pain was the cardinal symptom, with embolism to the lung, on the other hand, shortness of breath is usually predominant, and there may be no pain at all. Furthermore, definite evidences of a peripheral phlebitis are lacking, and there were no x-ray signs of pulmonary infarction.

Might not this man have had a myocardial infarct? There are several points in the case history that would seem to make such a condition not the diagnosis of choice. In the first place, as has been often pointed out, the pain associated with myocardial infarction does not typically occur abruptly as in this case but may build up with increasing intensity over a matter of minutes or even hours. Next, one notes the absence of arm discomfort and the presence of back and abdominal pain. Coronary occlusion with myocardial infarction certainly may be accompanied by pain in these last two areas, but perhaps such a complaint is more characteristic of a dissecting aneurysm. During the period of hospitalization no helpful findings, such as pericardial friction rub and electrocardiographic evidence of infarction, appeared. Finally, the past history as given contains no mention of angina pectoris or of previous episodes of pain that might have been interpreted as being of coronary origin.

Could the pathologist have given the medical man a surgical abdomen to discuss? If this man had a ruptured viscus, acute pancreatitis or mesenteric thrombosis, he showed an extraordinarily normal abdomen throughout, in addition to a well behaved intestinal tract, which did not even cause nausea or constipation. I cannot make a purely intra-abdominal diagnosis.

It seems that the one condition that fits this man's illness best is a dissecting aneurysm. He belongs to the right age group for such a diagnosis, and at this hospital, we have encountered more men than women with that diagnosis. The presence of significant hypertension is almost an invariable finding, and as with this man, the blood pressure is often sustained at a high level until the last moments of life. The first dissection in the media of the aorta may result in sudden excruciating and prolonged pain, which may be referred to both the thorax (anteriorly and posteriorly) and the abdomen. It is usual for these patients to survive for a matter of hours or days, rarely even for years, and sudden death at the onset is not found in most cases. The essentially negative physical examination is also consistent with such a diagnosis, and the lack of change in the electrocardiogram is an expected finding. Indeed, a changing electrocardiographic pattern would make one think of something other than a dissecting aneurysm.

At the age of nine years there had been an attack of rheumatic fever, allegedly with cardiac involvement, which had lasted three months. There were no recurrences. Before his illness, the patient's weight had been normal, afterward, he began to gain and at fourteen years of age weighed 216 pounds.

At the time of admission, the patient was sweating and rolling from side to side with pain. Extreme obesity — the patient weighed 270 pounds — made physical examination difficult. ONE HUNDRED AND SIXTY-SIXTH ANNIVERSARY

THE one hundred and sixty-sixth anniversary of the Massachusetts Medical Society, held at the Hotel Statler, Boston, on May 20, 21 and 22 was a highly successful affair. The total registration—1521—although not so large as that of last year, was impressive, and all who were present, including fellows, speakers, and exhibitors, seemed to be more than satisfied.

The annual meeting of the Council was held on the evening of May 19. Practically all committee reports, together with their recommendations, were routinely accepted on the basis of approval by the Executive Committee. Two matters are of general interest. Dr. Humphrey L. McCarthy, chairman

of the Committee to Meet with General Hawley, reported that the scheme whereby medical care to veterans was to have been covered by a contract between the Blue Shield and the Veterans Administration had been blocked. He suggested that the Society deal directly with the Veterans Administration under a gentleman's agreement, similar to the so-called 'Kansas Plan,' and the motions necessary to reopen the matter were passed by the Council. Under "new business," Dr. Merrill C. Sosman presented resolutions adopted jointly by several groups of radiologists, anesthesiologists and pathologists relative to the all-inclusive coverage of hospital services by the new contracts of the Blue Cross, which became effective on June 1. These organizations oppose any arrangement by a hospital with Massachusetts Hospital Service that permits the latter to guide or determine professional services, oppose the principle of comprehensive coverage on a per-diem basis of compensation because it fails to distinguish between hospital and professional services and recommend that charges for all professional services should be specifically excluded from all hospital-service plans. After the Council had voted to suspend its rules for procedure, approval of these resolutions was voted. The officers elected for the current year are as follows: president, Edward P. Bagg, president-elect, Daniel B. Rear-don, vice-president, Charles J. Kichham, secretary, Joseph Garland, treasurer, Eliot Hubbard, Jr., assistant treasurer, Norman A. Welch, ^{orator} Allen S. Johnson ^{going for all reserve Board and}

At the annual meeting, ^{there} ^{unanimously agreed} spreading the debt widely, Dr. Dwight O'Hara after ^{plans and more by individuals} inspiring talk covering "The Plan, which is currently being read the names of eleven ^{man or woman, the business} and automatic saving heretofore the Society in 1897 ^{and employees on payroll savings} ^{this plan} commercial banks will invite their depos- ^{on a card provided by the bank, to direct the bank to} ^{ke a monthly deduction equivalent to the purchase price} as a Series E, F or G Savings Bond. I should interpret the terminal episode as one of rupture of the column of blood through the adventitia of the aorta into the left pleural cavity, producing a slow steady leak. The chest x-ray findings might best be explained on that basis. Whether or not the aorta also ruptured into the pericardium I do not know. There is actually no necessity for assuming that it did. The presence of good pulsations in the dorsalis pedis artery bilaterally indicates that the dissection probably did not extend down to the common iliac arteries. I am unable to correlate such a diagnosis with the possibility of rheumatic heart disease and with the history of hemoptysis. The patient could have had mitral stenosis, if so, it must have been incidental and not a factor in the final illness.

I shall, therefore, make a diagnosis of a dissecting aneurysm secondary to a cystic necrosis of the media of the aorta.

DR MILFORD D SCHULZ The films of the chest made on entry show a tortuous and somewhat widened aorta, which can still be traced fairly well to the diaphragm. Twenty-four hours later the mid-portion of the descending aorta has become irregular in outline and is lost in an ill defined shadow that extends to each side of the mediastinum. A film made four days later shows fluid in the left pleural sinus, the mediastinum seems to be slightly wide and irregular, and the descending aorta is completely lost. The widening of the mediastinum, the irregularity of the aortic shadow and the loss of its contour can certainly be explained by hemorrhage into the mediastinum or into the wall of the aorta, which subsequently escaped into the left chest.

CLINICAL DIAGNOSIS

Dissecting aneurysm of aorta

DR PAUL'S DIAGNOSIS

Dissecting aneurysm of aorta, with rupture into left pleural cavity

ANATOMICAL DIAGNOSES

Dissecting aneurysm of aorta, with rupture into left pleural cavity
Cardiac hypertrophy, hypertensive type

PATHOLOGICAL DISCUSSION

DR BENJAMIN CASTLEMAN This man had a aortic dissection. The intimal tear occurred in the arch close to the origin of the left subclavian artery and the dissection had progressed from this point distally down to but not involving the iliac arteries. There was some dissection up the left common carotid and subclavian arteries but no involvement of the renal or mesenteric vessels. The exact point of external rupture could not be determined, but it was obvious as soon as the chest was opened that the rupture had occurred into the left pleural cavity because the latter was filled with both clotted and unclotted blood. From the history we know that the external tear had begun six hours before death and was therefore not a large one. There was enough time for some of the blood to extend extrapleurally into the retroperitoneal tissues around the upper abdominal aorta — even to surround the left adrenal cortex on its upper and posterior surfaces.

As usually observed, there was slight arteriosclerosis of the aortic intima, the cause of the dissection being medial necrosis cystica. The heart was hypertrophied, weighing 630 gm.

It is interesting to note that this man's symptoms correlate strikingly with the anatomic findings. The initial tear was in the left arch, with dissection up the left great vessels, and the initial symptom was pain in the neck. The dissection went down the descending aorta, thus accounting for the abdominal symptoms. There was practically no chest pain, which corresponds with the absence of dissection in the ascending aorta, unlike the great majority of cases of aortic dissection, in which the ascending portion is involved.

Dr. Kilburn received his degree from Dartmouth Medical School in 1911. He was a member of the staffs of the Wesson Memorial and Springfield hospitals, and was a member of the American Urological Association.

TOBEY—George L. Tobey Jr., M.D., of Brookline, died May 20. He was in his sixty-sixth year.

Dr. Tobey received his degree from Harvard Medical School in 1903. He served in World War I as a captain in the Medical Corps. He was a member of the staffs of the Massachusetts General, Boston City, Brooks, New England Deaconess and New England Baptist hospitals and was consulting surgeon at the Massachusetts Eye and Ear Infirmary. He was a former president of the American Otolological Society and a former vice-president of the American Academy of Ophthalmology and Oto-Laryngology. He was a member of the American Laryngological Association, American Laryngological, Rhinological and Otolological Society and New England Otolological and Laryngological Society and a fellow of the American College of Surgeons and the American Medical Association.

His widow, a daughter, a grandson and two brothers survive.

CORRESPONDENCE

PREVENTION OF ANTHRAX

To the Editor—The Massachusetts Department of Labor and Industries has recently passed rules and regulations designed to prevent anthrax in industries where animal products are handled. This step was taken after a survey of these plants by the supervising industrial inspector of the Division of Industrial Safety and the physician of the Division of Occupational Hygiene. The survey followed what might be called an "epidemic" of anthrax among the workers in four relatively small concerns handling hair and wool. Within the year there were seven cases with four deaths.

Study of collected data shows that in Massachusetts between 1933 and 1940, there were 34 cases of anthrax with 4 deaths, a mortality of 12 per cent, while from 1940 to 1945, there were 21 cases with 7 deaths, a mortality of 33 per cent. The increase of the disease on the part of physicians outside the State serving in the tanneries of Massachusetts appeared to be the greatest factor in this high mortality rate. Lack of knowledge of the worker and his employer regarding the malignant character of anthrax was also a serious factor. Finally, it seems quite naturally see little of this disease and, in experience, have been unaware of the heroic measures necessary for its successful treatment. Penicillin fortunately appears to be specific therapy if given early and in large doses.

The following table analyzing the work of the anthrax virus is of importance in bringing out these facts:

TYPE OF WORK	NO OF CASES	NO OF DEATHS	MORTALITY %
Tannery	5	1	3
Hair and bristle	7	5	71
Wool	7	3	43
Transportation	4	2	50
Agriculture	2	0	0
	55	11	

Section 9 of the rules and regulations requires the employer to engage a competent physician aware of the anthrax hazard and further to arrange that a worker "with any sore, boil or pimple" on the exposed parts of his body be immediately seen by the designated physician. The remainder of the rules implement this regulation and outline required washing facilities.

Unfortunately, there is no known practical method of destroying anthrax spores in animal products for industrial use without interfering with the commercial value of the material. Animal products imported into this country from the Orient, South America and Europe, notably central European countries, are potential sources of anthrax. Furthermore, recent information from the Veterinary Section of the United States Public Health Service states that anthrax spores occur in the soil and hence on the animals of all but five states in this country, with the heaviest contamination in Texas, Louisiana, South Dakota and California.

There are no interstate quarantine laws for regulating the distribution of anthrax infected animal products. Federal inspection of imported animal material, formerly carried out by the Bureau of Animal Industry, has been discontinued, since animal anthrax in this country is controlled by anthrax vaccine. Unfortunately, the anthrax vaccine does not rid the animal's hide and hair of anthrax spores, nor is there an anthrax vaccine available for human use.

An understanding of the problem by employer, worker and physician should eliminate fatalities in industries where anthrax is a hazard.

A copy of these rules and regulations may be obtained by writing or phoning the Massachusetts Division of Occupational Hygiene, 286 Congress Street, Boston 10 (phone, LIBerty 0183).

BOND-A-MONTH PLAN

To the Editor—The national debt amounts to \$1840 for each man, woman and child in America. The management of this debt will affect prices, employment, wages, how much people can buy and what their savings will be worth. It will affect everyone in his work and at his dinner table.

Wise management of the debt will help level off the economic peaks and valleys that make rough going for all. The Treasury Department, the Federal Reserve Board and the American Bankers Association are unanimously agreed that wise management includes spreading the debt widely, that is, fewer bonds held by banks and more by individuals.

Through the Bond-a-Month Plan, which is currently being announced, the professional man or woman, the business executive and the self-employed are being given the same opportunity for systematic and automatic saving heretofore enjoyed only by industrial employees on payroll savings. Under this plan, commercial banks will invite their depositors, on a card provided by the bank, to direct the bank to make a monthly deduction equivalent to the purchase price of a Series E, F or G Savings Bond. The bank makes the deduction, charges the account for the purchase price and, during the month, mails the bond to the customer. The deductions may be discontinued at any time by authorization.

The plan combines a way to invest regularly in the best possible security and at the same time to help in the wise debt management so essential to the national welfare.

The Bond-a-Month Plan deserves serious consideration. Further details may be obtained at one's bank.

College of Medicine, and director of the Medical Service, College Division, King's County Hospital, Brooklyn, New York. This paper, entitled "Clinical Significance of Circulatory Peculiarities of Some of the Vital Organs," was published in the May 22 issue of the *Journal*.

The annual dinner was attended by 418 fellows and guests. The principal speaker was Dr. Shoulders, who spoke on the topic, "The Responsibilities of the Medical Profession."

The scientific sessions were well attended, as were the section meetings and the exhibits. The paucity of scientific exhibits was unfortunate but necessitated by a cutting down of the space permitted. It is to be hoped that in the future some arrangement can be made whereby a larger number of such exhibits can be accommodated.

Dr. Sidney C. Wiggin, the other members of the Committee on Arrangements and Mr. Robert St. B. Boyd, executive secretary of the Society, deserve great praise for making possible a meeting that was so successful.

ANTHRAX

ALTHOUGH relatively few physicians have ever seen a case of anthrax in their practices, the disease does occur with enough frequency to constitute a true occupational hazard, particularly in a state like Massachusetts in which the handling of hides, wool

Dissection of animal products is widespread in industry. Left pleural elsewhere in this issue of the to the fact that from 1940 cases of anthrax, with 7 per cent. Furthermore, it these fatalities could

FIGURE 1

admission and another five days later showed changes consistent with left-axis deviation, no indication of infarction was observed in either film. Shortly after admission the serum amylase level was 20 units, and the nonprotein nitrogen 23 mg per 100 cc.

tion of animal products, such as hides, skins, wool hair, bones, bristles and so forth. These rules and regulations chiefly concern measures to prevent anthrax, such as dust control, the maintenance of clean and sanitary conditions in the plant, and washing facilities, adequate protective covering and individual clothes lockers for employees, as well as a drying room for work clothes. In addition, a responsible plant official is required to arrange for immediate medical attention in all suspected cases, each employee must report any "sore, boil or pimple" and all suspicious lesions must be seen by a designated physician who has "a thorough knowledge of the problems of anthrax." Failure to conform to the statute is punishable by fine.

Undoubtedly most of these requirements have been met for many years by large industrial firms, such as tanneries, in which the employers, employees and company physicians are fully aware of the anthrax hazard. But in small concerns and in those in which the disease occurs infrequently proper precautions have not been taken, and when anthrax has appeared, it has not been diagnosed early enough in the majority of cases for treatment to be as effective as it should be. These new rules and regulations, if properly enforced, should go far in lowering the morbidity and mortality of the disease.

BOND-A-MONTH PLAN

To the Editor: The national debt amounts to \$1840 for each man, woman and child in America. The management of this debt will affect prices, employment, wages, how much people can buy and what their savings will be worth. It will affect everyone in his work and at his dinner table.

Wise management of the debt will help level off the economic peaks and valleys that make rough going for all. The Treasury Department, the Federal Reserve Board and the American Bankers Association are unanimously agreed that wise management includes spreading the debt widely, that is, fewer bonds held by banks and more by individuals.

Through the Bond-a-Month Plan, which is currently being announced, the professional man or woman, the business executive and the self-employed are being given the same opportunity for systematic and automatic saving heretofore enjoyed only by industrial employees on payroll savings. Under this plan, commercial banks will invite their depositors, on a card provided by the bank, to direct the bank to make a monthly deduction equivalent to the purchase price of a Series E, F or G Savings Bond. The bank makes the deduction, charges the account for the purchase price and, during the month, mails the bond to the customer. The deductions may be discontinued at any time by authorization.

The plan combines a way to invest regularly in the best possible security and at the same time to help in the wise debt management so essential to the national welfare.

The Bond-a-Month Plan deserves serious consideration. Further details may be obtained at one's bank.

CORRESPONDENCE

PREVENTION OF ANTHRAX

To the Editor: The Massachusetts Department of Labor and Industries has recently passed rules and regulations designed to prevent anthrax in industries where animal products are handled. This step was taken after a survey of these plants by the supervising industrial inspector of the Division of Industrial Safety and the physician of the Division of Occupational Hygiene. The survey followed what might be called an "epidemic" of anthrax among the workers in four relatively small concerns handling hair and wool. Within three years there were seven cases with four deaths.

Study of collected data shows that in Massachusetts between 1935 and 1940, there were 34 cases of anthrax with 4 deaths, a mortality of 12 per cent, while from 1940 to 1945, there were 21 cases with 7 deaths, a mortality of 33 per cent. Ignorance of the disease on the part of physicians outside those serving in the tanneries of Massachusetts appeared to be the greatest factor in this high mortality rate. Lack of knowledge of the worker and his employer regarding the malignant character of anthrax was also a serious factor. Finally, physicians quite naturally see little of this disease and, in our experience, have been unaware of the heroic measures necessary for its successful treatment. Penicillin fortunately appears to be specific therapy if given early and in large doses for a long period.

The following table analyzing the work of the anthrax victims is of importance in bringing out these facts:

RESTORATION OF LICENSES

To the Editor At a meeting of the Board of Registration in Medicine held May 16, it was voted to restore the registration to practice medicine to Dr Julius Shubert, 26 Esmond Street, Dorchester, whose registration was revoked June 6, 1945

H QUIMBY GALLUPE, M D, *Secretary*

State House
Boston

To the Editor At a meeting of the Board of Registration in Medicine held May 16, it was voted to restore the registration to practice medicine to Dr Aaron O Bernstein, formerly of 98 Main Street, Gardner, whose registration was revoked June 7, 1945

H QUIMBY GALLUPE, M D, *Secretary*

State House
Boston

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Obstetrical Practice By Alfred C Beck, M D, professor of obstetrics and gynecology, Long Island College of Medicine and obstetrician and gynecologist-in-chief, Long Island College Hospital. Fourth edition. 4°, cloth, 966 pp., with 1068 illustrations. Baltimore: Williams and Wilkins Company, 1947. \$7.00

This standard textbook by an outstanding authority in his field first published in 1935 and translated into Portuguese in 1940, has been revised to bring the text up to date. The sections on implantation and placentation have been rewritten and simplified. The use of penicillin in the prevention of congenital syphilis is discussed in the sections on syphilis and pregnancy and puerperal infection. A new chapter on analgesia, amnesia and anesthesia has been added. The picture of Dr Oliver Wendell Holmes shows him as an old man. One taken about 1843 would have been more suitable. A list of selected references is appended to each chapter. The text is printed with a good type, and the illustrations are adequate. The price is surprisingly low for the size of the volume. The book is recommended for all medical libraries.

Essentials of Endocrinology By Arthur Grollman, Ph D, M D, professor of medicine and chairman, Department of Experimental Medicine, Southwestern Medical College, and attending physician and consultant in endocrinology, Parkland Hospital, Dallas, Texas. Second edition, revised and enlarged. 8°, cloth, 644 pp., with 132 illustrations. Philadelphia: J B Lippincott Company, 1947. \$10.00

This standard work, first published in 1941, has been revised to include new material published during the past six years. Emphasis has been placed on the clinical aspects of endocrinologic disorders in which most of the recent advances have been made.

The material is well organized, and each chapter is documented with a select list of references to the recent literature, analyzed in the text. The book is well published. The type is especially good, and the illustrations are excellent. The volume is heavy for its size, owing to the use of coated paper, and special tables of endocrinologic products are printed on the inside linings of the front and back covers—an unfor-

tunate practice for valuable material. The volume should be in all medical libraries for reference purposes and should prove useful to physicians interested in the subject.

Synopsis of Operative Surgery By H E Mobley, M D, chief in surgery, St Anthony's Hospital, Merrilton, Arkansas. Second edition. 8°, cloth, 416 pp., with 383 illustrations, including 37 in color. St. Louis: C V Mosby Company, 1947. \$6.00

This manual for students of surgery, first published in 1940, has been revised and brought up to date. The beginning chapters are devoted to anesthesia, postoperative care and surgical technic, and the others to major operations. The drawings are clear and well executed. The material is well arranged and well printed, although the type is small. The manual should prove useful as a reference book for students and surgeons. The price seems excessive for the size of the volume.

The Head, Neck, and Trunk Muscles and motor points By Daniel P Quiring, Ph D, head of Anatomy Division, Cleveland Clinic Foundation, and associate professor of biology, Western Reserve University. 8°, cloth, 115 pp., with 101 illustrations. Philadelphia: Lea and Febiger, 1947. \$2.75

This small book is designed as a companion volume to the author's *The Extremities*, previously noted in the *Journal*. The individual muscles of the head, neck and trunk are portrayed, together with their chief arterial and nerve supply. The diagrams are excellent and based on original dissections and on references to standard anatomies. The volume should be useful to students and physical therapists, and to surgeons for reference purposes.

Ulcer of the Stomach, Duodenum, and Jejunum By Ralph C Brown, M D, Professor of Medicine, University of Illinois College of Medicine, and attending physician, Presbyterian Hospital, Chicago. 8°, cloth, 172 pp. with 40 illustrations. New York: Oxford University Press, 1946. \$2.25 (Reprinted from *Oxford Loose-Leaf Medicine*).

The author in this small book discusses the pathology, symptoms, diagnosis and treatment of peptic ulcer in the light of the latest knowledge of the subject. Special emphasis is placed on differential diagnosis and treatment. The book should prove useful to physicians in general practice.

Diseases of the Nose and Throat By Charles J Imperator, M D, consulting laryngologist, Harlem Hospital and Nyack General Hospital, and consulting bronchoscopist, Manhattan Eye, Ear and Throat Hospital, Flower and Fifth Avenue Hospitals, and Riker's Island Hospital, and Herman J Burman, M D, director, Department of Otolaryngology, Harlem Hospital, instructor in otolaryngology, Columbia University College of Physicians and Surgeons, and assistant visiting otolaryngologist, Presbyterian Hospital and Vanderbilt Clinic. Third edition. 8°, cloth, 576 pp., with 480 illustrations. Philadelphia: J B Lippincott Company, 1947. \$12.00

This standard textbook, first published in 1935 and translated into Spanish in 1942, has been revised to incorporate the advances in the subject since the publication of the second edition in 1939. A new section on the vitamins has been added, and the use of penicillin and the sulfonamides has been discussed especially in relation to intracranial complication. The chapter on radiation therapy has been completely revised and brought up to date. The material is well organized. A two-column format is used to save paper, but the type and printing are good and the volume is well published. The book is recommended to medical libraries as a reference source.

THE SURGERY OF CANCER*

CHARLES HUGGINS, M D †

CHICAGO

LET us stand back for a moment and inspect the edifice of knowledge already erected on the surgery of cancer. This paper considers the history of the basic concepts involved in the modern surgery of tumors and attempts to demonstrate the inter-relation in the growth of these ideas, this perspective will permit a prognosis to be uttered for the surgical discipline in cancer. Obviously all three efforts must be brief and sketchy, a list of all the contributors to cancer surgery would read like the catalogue of the ships in the second book of the Bible or the begat series in Genesis.

I suppose that a defense of the historical approach is never necessary. Although its methods are occasionally tiresome to nonprofessional historians, history is often of interest, and it becomes important if one can see in past performance a clue for future advance.

It might well be asked why the surgery of cancer should be discussed at a celebration of the introduction of anesthesia. There are several reasons — the development of the modern concepts of neoplastic disease was coeval with and largely consequent on the development of modern surgery. Clearly, before pain had been controlled and the relaxation of muscles had been secured, surgical operations on internal organs were possible to such a limited extent as to be practically negligible. Certainly, the surgery of tumors of the viscera comprises a large percentage of the surgical task and the opening of this field awaited anesthesia for its development. Also, the famous operation that introduced the use of ether in surgery was performed by Dr. Warren on a vascular tumor of the neck.

A century ago cancer was emerging from a period of empiricism and superstition in which the disease had been completely shrouded in mystery. Some attempts at description of tumors had been made, but medicine was in the Paleozoic age, innocent of laboratories and nearly devoid of the correlation of

the clinical state with dead-house findings, despite Morgagni's *De Sedibus*.¹ Before 1846 few studies of cells or tissues had been made, and cellular pathology was unknown. At that time, in his second published paper entitled "Weisses Blut," Virchow had just attributed correctly the pale character of the blood in leukemia to an excess of white corpuscles.

As representative of early American surgical thought about neoplasms I cite the experience of Warren,² who in 1839 described the status of cancer surgery at the Massachusetts General Hospital just before the discovery of anesthesia. He stated that an "exact discrimination between different kinds of tumors is very important to the practitioner of surgery." He added "The opinion he may offer in such cases will soon be put to a severe and public test, for the course of these diseases lies open to the view of the patient and his friends and the result must be known to them." At that time, however, so little was known about disease that diagnosis was often impossible. The differentiation, for example, between granulomas and neoplasm was difficult, although scrofulous lesions were well recognized. Cancer, according to Warren, was not regarded as a specific disease. "It has a variety of forms, of causes and of habitudes of action. There is nothing specific in it unless you call its incurable disposition specific." A constitutional predisposition to cancer was recognized, and the disease was thought to occur frequently after violence. Tobacco was recognized as a factor in lesions of the mouth and lower lip.

Two species of cancer were regarded as separate entities easily distinguishable from each other — namely, carcinoma and fungoides. Carcinoma, or scirrhus, was characterized by its hardness and its tendency to ulceration. The term "fungoides" (sarcoma) was used for tumors that were soft and had a tendency to bleed easily.

In cancer of the breast Dr. Warren recognized that "enlargement of the glands in the axilla commonly took place from the extensions of the diseased action along the absorbent vessels," and that

when the lymph nodes were enlarged the disease was usually incurable. Thyroid tumors were believed to be a disease of inland countries and of territories situated on the banks of rivers, and the recommended treatment was the internal use of burnt sponge and of iodine. Tumors were frequently of tremendous size before operation was undertaken, often weighing ten to twenty pounds.

The surgical treatment, which was largely superficial, was confined to tumors of the head, except for the cranial contents, and the neck, breast, extremities and skin. Strong men had important roles in the operation as technical assistants. Extensive operations on the jaws were often undertaken. The surgical procedures were threefold, consisting of excision, mass ligation with stout cords transfixing the tumors at right angles by the aid of needles either straight or crooked or the actual cautery. In procedures of excision skin flaps were raised when possible and resutured loosely at the end of the operation. Bleeding and air embolism often provided a serious difficulty.

The modern reader is impressed by three characteristics of preanesthetic surgery: the deficiency of pathological knowledge at that time, the often reckless celerity of the surgical procedure and its attendant agonies. The surgeons of a hundred years ago were men of intelligence whose mental powers we can, with charity, rate equal to our own. Was everything that they did inferior to the practices of today? Obviously not, one gains the opinion that in anatomic knowledge, at least, the surgeon was rather better informed than the average surgeon today, since anatomic dissection was nearly the only investigative outlet for diligent and thoughtful surgeons.

The necessity for rapid operations required that the procedure be well thought out. The following advice of Warren is still apposite to surgical practice:

An operator should not be satisfied with tracing a plan in his mind only. It should be fairly written out, and he should imagine all possible difficulties and embarrassments and put them in writing.

The evolution of the surgery of cancer from this elementary position was biphasic and rested on the development of some working concepts of the disease, as well as on the establishment of better surgical ideas. Both aspects had to be developed simultaneously, since both required much the same methods—the methods of science. Progress in medicine has always been dependent on the advances of pure science to a peculiar extent. A secondary or reading knowledge of science has usually provided an insufficient stimulus for the discovery or application of scientific knowledge to the clinical problems. Working with phenomena gives a vastly more intimate familiarity with the effects of nature than books do, and for this reason the greatest advances in medicine have been made

by active participants in research. Also, the scientific indoctrination of close observation and precise thought has provided a fresher attitude to the puzzles of medicine than was possible with bedside study alone. These are concepts of primary importance because they provide historical justification for the necessity of surgical laboratories and research workers in the clinical departments.

The history of cancer surgery also emphasizes the influence of the schools of surgery, which have always formed around energetic and intelligent leaders, this fact is reiterated below. There are two obvious reasons why the momentum of a great surgical school forms a self-catalyzing cycle: a successful department is apt to attract the brilliant students, who in turn contribute to the success of the clinic. Thus, the school of pathology founded by Johannes Müller in Berlin in addition to the founder had two members who made large contributions to the knowledge of tumors.

The concept of organization of the body in cellular units depended on the development of the achromatic microscope by Silligues, of Paris, in 1824. Müller³ himself soon undertook the microscopic study of cancer cells (his findings were published in 1838), but the morphologic studies of that time were at a primitive level. In 1852 one of his students, Adolf Hannover,⁴ of Copenhagen, set cancer of the skin apart from other cancers because of its low rate of growth and coined the name "epithelioma" for this group of neoplasms, which he regarded as more benign than the tumors of the viscera. Another of the contributions of Hannover was the advocacy of biopsy of superficial lesions to establish a pathological diagnosis. Rudolf Virchow,⁵ who graduated from the University of Berlin in 1843, was another of Müller's pupils who exerted a great influence on pathology—indeed, he was one of the fathers of this discipline. Virchow's great contribution was the recognition of the importance of the cell in pathological processes. Before Virchow the cellular structure of cancerous tissue had been recognized, but the cell had been thought to be subsidiary to an underlying humoral "blastema," which was regarded as a sort of primary fluid from which all structures arose. Haagensen⁷ estimates Virchow's discovery as follows: "With his dictum 'Omnis cellula e cellula' Virchow swept away this erroneous conception and firmly established the cell as the fundamental unit in which disease processes operate." This law, which states that all living cells represented an uninterrupted continuum, has had functional value in the elucidation of disease. No one has been able to disprove it, and it has been largely unquestioned recently, although it is probably wrong. Perhaps, in some of the back waters and bayous of the world molecular conjunctions are occurring to effect reproducibility or life.

*Haagensen⁷ has compiled an interesting bibliography of some of the source material concerning the early history of the development of the pathology of cancer.

The term "sarcoma" had been used by Galen in a restricted sense in describing abnormal fleshy growths in the nares, and as already mentioned, this word had been adopted by surgeons in the sense of any soft and highly vascularized growths. The modern definition of sarcoma was laid down by Virchow⁶ as an abnormal growth belonging to the general group of the connective tissues. Virchow, however erroneously believed that all malignant tumors arose from connective tissue.

The definition of carcinoma as an atypical epithelial growth of either surface or internal lining cells was not agreed on until the work of Thiersch⁷ and Waldever.⁸ In 1865 Carl Thiersch, of Erlangen, studied skin carcinoma by means of free hand incisions made with a razor, staining the slices with ammoniated carmine. He was able to establish the topographic continuity of deep-seated masses of subcutaneous malignant epithelial cells with the surface layer and concluded that they arose from the epithelium rather than from connective tissue. He also showed that in this condition the presence in the lymph nodes of nests of cancer cells was due to the metastasis of the cells of the skin carcinoma. The proof ably developed by Thiersch of the epithelial origin of cutaneous carcinoma was confirmed in Breslau by Waldever, who in 1872 extended the idea to show that adenocarcinoma arose from epithelium in all other parts of the body, the evidence was simple and consisted of the demonstration of the physical continuity between the normal epithelium and the carcinoma.

Advances in the general field of surgery made possible the surgical treatment of external cancers, but the development of surgical technics for the treatment of internal cancer required the discovery and application of the principles of surgery. The formulation of the principles of surgery made tremendous strides in the last century and is still going on. These principles are probably not yet definitive or insusceptible of clarification, and consequently they cannot be regarded as a finished product incapable of improvement.

The great principles of surgery are perhaps six in number: control of pain, a deliberate operative procedure undertaken without haste, adequate exposure of the lesion, control of bacteria, maintenance of the optimum physiologic state, and accurate preoperative diagnosis.

Three of these principles were made possible by the introduction of ether anesthesia, which is no doubt the greatest single contribution in the development of surgery. The abolition of pain not only was a humane measure of significance but also made possible an unhurried and thoughtful operation with adequate exposure of the lesion. No longer was it necessary to make a reckless attack to correct an abnormal process in which haste often led to complicating accident.

Control of bacteria next received attention since a brilliant operative maneuver frequently became undone in the postoperative period. The control of bacteria in the external environment, being simpler, was developed first and in the last century, whereas chemotherapy against the internal bacterial pathogens has been introduced only recently. The concepts and experiments of Lister^{10, 11} remain among the simplest and most productive products of the surgical mind. The Listerian ideas and the use of phenol, together with the milder antiseptic agents that were developed later remain important. The killing of bacteria by sublimate and heat sterilization led to the introduction of the aseptic technic by von Bergmann,¹² and this was a significant practical addition to antiseptics. Some partial control of internal bacteria through chemotherapy has been achieved only in the last fifteen years dating from the introduction of prontosil in 1932 by Domagk¹³; this discovery of course was greatly improved with the later elucidation of its prosthetic group, the sulfonamide nucleus and its mode of action by way of competition with para-amino benzoic acid. The use of natural antibiotic products elaborated by soil bacteria and molds with their partial purification through the work of Dubos and his luckier contemporaries, Fleming, Waksman and others, has profoundly affected surgical practice.

The maintenance of the optimum physiologic state did not arise as a full-blown concept until the last decade. Since ether had rendered possible extensive operations, the necessity to prevent exsanguination became apparent, and the control of bleeding was obtained by many ingenious technical advances. An important technical detail was the application of the lock device to hemostatic forceps by Spencer Wells and the French school (Pean), this was of practical value since it made possible such movements as that of the Halsted¹⁴ school which introduced meticulous and immediate hemostasis. The recognition of the blood groups of man by Landsteiner¹⁵ (1901) and the development of blood transfusion and the blood substitutes, such as plasma and other substances, saved many lives. After many years it developed that hemostasis and blood transfusion were not enough, the general nutritional state of the organism regarding fluid, electrolytes, vitamins and carbohydrates has importance as well. Within recent years, largely as a result of the work of Cannon and his associates¹⁶ in Chicago, it has been appreciated that the body proteins are of particular significance since states of protein deficiency are associated with a deficient antibody pool in the organism and consequently with deficient natural defences, obviously, the protein status of the surgical patient cannot be disregarded or the treatment of protein deficiency neglected. Just as Virchow recognized that the basis of pathology was the tissues and their cells, the surgeon must realize that a surgical procedure is done on

when the lymph nodes were enlarged the disease was usually incurable. Thyroid tumors were believed to be a disease of inland countries and of territories situated on the banks of rivers, and the recommended treatment was the internal use of burnt sponge and of iodine. Some partial control of internal bacteria through chemotherapy has been achieved only in the last fifteen years, dating from the introduction of prontosil in 1932 by Domagk¹³; this discovery, of course, was greatly improved with the later elucidation of its prosthetic group, the sulfonamide nucleus and its mode of action by way of competition with para-amino benzoic acid. The use of natural antibiotic products elaborated by soil bacteria and molds with their partial purification through the work of Dubos and his luckier contemporaries, Fleming, Waksman and others, has profoundly affected surgical practice.

The maintenance of the optimum physiologic state did not arise as a full-blown concept until the last decade. Since ether had rendered possible extensive operations, the necessity to prevent exsanguination became apparent, and the control of bleeding was obtained by many ingenious technical advances. An important technical detail was the application of the lock device to hemostatic forceps by Spencer Wells and the French school (Pean), this was of practical value since it made possible such movements as that of the Halsted¹⁴ school, which introduced meticulous and immediate hemostasis. The recognition of the blood groups of man by Landsteiner¹⁵ (1901) and the development of blood transfusion and the blood substitutes, such as plasma and other substances, saved many lives. After many years it developed that hemostasis and blood transfusion were not enough, the general nutritional state of the organism regarding fluid, electrolytes, vitamins and carbohydrates has importance as well. Within recent years, largely as a result of the work of Cannon and his associates¹⁶ in Chicago, it has been appreciated that the body proteins are of particular significance since states of protein deficiency are associated with a deficient antibody pool in the organism and consequently with deficient natural defences, obviously, the protein status of the surgical patient cannot be disregarded or the treatment of protein deficiency neglected. Just as Virchow recognized that the basis of pathology was the tissues and their cells, the surgeon must realize that a surgical procedure is done on

protoplasm and that the chemical reactions and functions of this jelly of the cells are of considerable significance to him

Of particular importance in cancer surgery is the recognition of a neoplasm through accurate diagnosis and in an early stage of the life of the tumor. Clearly, the surgery of advanced tumors is a pessimistic performance. The diagnosis awaited physical and chemical means for its development. The physical instruments of greatest value were the electric lamp of Edison and the x-rays of Roentgen¹⁷ (1895). The application of tiny electric lamps to the cystoscope by Nitze¹⁸ in 1887 made endoscopic cystoscopy possible and led to the development of urology as a specialty. The discovery influenced medicine considerably, and Nitze acknowledged in his first paper that the diagnosis of bladder tumors was the great triumph of his method. Menlo Park also made possible direct examination of the rectum, sigmoid, stomach, esophagus, bronchi and other previously inaccessible regions. The impact of Roentgen's discovery on diagnosis was so large as to be incalculable and its use revolutionized the detection of disease in every field of medicine.

Chemistry has also contributed to the diagnosis of surgical disease, especially in cancer. Indirect methods concern concentration of radio-opaque dyes in the gall bladder and urinary tract as introduced by Graham and Cole¹⁹ (1924) and Binz²⁰ (1930) respectively. Direct methods of chemical diagnosis of cancer are concerned with the urinary excretion of proteins derived from cancer cells, such as the albumose of Bence-Jones²¹ (1848) in multiple myeloma, of melanin in melanosarcoma and of chorionic gonadotropin in testicular tumor as discovered by Zondek²² in 1930. In prostatic cancer tumor products are also detectable in the blood in the form of certain enzymes, as demonstrated by Gutman and Gutman²³ in 1938. Since the aim of diagnosis is to recognize disease without seeing the patient, it is clear that the laboratory must assume large importance as the science develops.

The surgical problems of cancer were largely brought into focus and the principles of surgical treatment developed in the evolution of the handling of patients with cancer of the female breast. This was natural for several reasons, especially because mammary cancer is frequent. Contributory also were the facts that the primary lesion and the lymph nodes draining the breast were superficial and easy to examine and that the surgical treatment did not involve violation of a body cavity. In 1867 Moore,²⁴ of London, was one of the first surgeons to appreciate that the recurrence of a breast cancer was due to incomplete removal of the tumor, it had previously been thought that these lesions represented an entirely new neoplasm developing on an organic or constitutional basis. Moore proposed that when the adjoining skin or axillary lymph nodes are involved by cancer they should be removed in one

mass, since it is desirable to avoid cutting into the tumor or even exposing it at operation.

The value of this concept of block dissection was confirmed and the technic widened by Volkman who discovered that cancer cells frequently infiltrated the fascia covering the pectoralis major muscle so that this fascia was routinely removed by him. Halsted¹⁴ (1890) showed that technically the best way to do this was to remove the pectoral muscles, and he also advocated the removal of large amounts of skin surrounding the tumor. Each technic resulted in a larger percentage of cures than previously, and axillary dissection became a routine whether or not the lymph nodes were suspected of being grossly involved by the tumor.

The surgery of visceral cancer was developed in a definite time sequence — namely, abdominal and genitourinary tracts, central nervous system and lastly the chest.

Visceral surgery could not be developed before anesthesia or antiseptics, but with these aids the essential methods were rapidly introduced. The principal methodology of abdominal surgery was devised largely in the Billroth school in Vienna. Theodor Billroth was a magnetic leader and a tireless and intelligent worker as well as a *bon vivant*. His school worked out many of the technics of stomach and bowel resection on animals in the surgical laboratory, and this approach in itself was a contribution to surgical investigation of first-class importance. In 1881 Billroth²⁵ made the first resection of the pylorus for gastric cancer and performed many intestinal resections between 1878 and 1883. A Billroth pupil, Anton Wölfler,²⁶ devised the technic of gastroenterostomy in 1881, and another student, Mikulicz²⁷ (1903) introduced obstructive resection with exteriorization of the large bowel for carcinoma, both procedures advanced cancer surgery. Surgeons throughout the world soon added many technical refinements to abdominal surgical technic.

Tumors of the urinary tract were seldom treated before the advent of precise diagnostic methods. The first tumor of the bladder to be removed by *sectio alta* was operated on by Billroth²⁸ in 1872, the diagnosis having been made by urethrotomy with digital palpation of the neoplasm in the vesical cavity. Cystoscopy, ureteral catheterization and pyelography converted a *terra incognita* into a field characterized by diagnostic precision. Although the electrically lighted cystoscope of Nitze had made possible the diagnosis of bladder tumors, Nitze had unsuccessfully tried to catheterize the ureters, since he had no way of manipulating the tip of the catheter. A remarkably interesting Cuban, Joaquin Albarran,²⁹ professor of urology in Paris, solved this problem by devising a cystoscope with a movable arm to provide leverage and thus to guide the catheter into the ureteral ostium. Ureteral catheterization and the subsequent introduction of contra-

radiography by Voelcker and von Lichtenberg³⁰ (1903) were real steps forward in the diagnosis of renal neoplasms. The perineal approach to the prostate and total prostatectomy introduced by Young³¹ (1906) made possible the excision of early cancer of the prostate gland. The introduction of high-frequency currents and their application to cystoscopic fulguration by Beer³² have added much to the treatment of vesical neoplasms.

The surgery of tumors of the nervous system was developed chiefly because of the efforts of the Queen Square group in London and of Cushing³³ and Dandy^{34, 35} in the United States. In 1885 Bennett and Godlee³⁶ first localized and removed a brain tumor, although unfortunately the wound in this case became infected and the patient died a month later of meningitis. Gowers and Horsley³⁷ in 1888, first localized and extirpated a tumor of the spinal cord, the patient making a complete recovery.³⁸ The contributions of Cushing³³ in the field of tumors of the nervous system were manifold, perhaps his most significant contributions were the development of a refined deliberate surgical technic, new approaches for the cerebellar tumors and a classification of neoplasms of the brain. The Cushing methods transformed what was previously a highly dangerous operative attack into a comparatively safe one. The fertile mind of another Hopkins product, Walter Dandy,^{34, 35} contributed the diagnostic tools of encephalography and ventriculography and devised many clever procedures — for example, a new surgical approach for the treatment of tumors of the acoustic nerve.

The development of the surgery of intrathoracic neoplasms was delayed until methods were found to prevent pulmonary collapse. The solutions offered for the problem became progressively simpler. In the research laboratory of an industrial concern today there is a sign that reads as follows: "When the solution of your problem is known, it will be found to be simple." Methods of preventing collapse of the lung, such as the differential pressure cabinets of Sauerbruch,³⁹ were cumbersome and difficult to use and were soon replaced by intratracheal intubation, the present methods of dispensing anesthetic gases from tanks under pressure allow the lung to be kept at any required degree of expansion or collapse by the use of a simple facial mask.

Partial pneumonectomy for tumors of the lung was accomplished by Sauerbruch³⁹ in 1926 and by Churchill⁴⁰ in 1933 with good results, and the entire lung was first removed for cancer by Graham and Sager⁴¹ in 1933. In the early cases fear of the huge empty pleural cavity was present, and the space was obliterated by thoracoplasty, this was a groundless fear, however, and Rienhoff⁴² (1933) showed that the cavity became obliterated by compensatory pulmonary expansion, so that plastic operations on the chest wall were dispensable.

The surgical treatment of tumors of the thoracic esophagus was late in development. In 1913 the first successful esophagectomy was carried out in New York by Torek,⁴³ who resected the esophagus, bringing the proximal portion externally through a cervical incision and feeding the patient by gastrostomy. This technical procedure was superseded by the work of the Japanese surgeon Ohsawa,⁴⁴ who in 1934 performed successful transthoracic resection of the neoplasms of the esophagus and of the cardia of the stomach with esophagojejunostomy. This procedure has been refined and made less dangerous by the work of many thoracic surgeons, especially in America.

In orthopedic surgery the development of basic principles has influenced the surgery of bone sarcoma. Codman recognized the fact that giant-cell tumors of bone were benign lesions that did not require amputation of the limb. In 1938 Phemister⁴⁵ discovered that malignant bone sarcomas could often be cured by local resection of the involved part with preservation of the extremity through bone grafting. This is in accord with the ideas of modern cancer surgery — that is, there is no need to cut off the head to cure a brain tumor.

In the nineteenth century surgeons were concerned with descriptive pathology, with concepts of the grosser aspects of cancer and with the evolution of some of the simpler principles of surgery. With the close of this period the gross description of tumors had been rather well made, and the era of laboratory experimentation was fairly begun. Until disease can be reproduced in the laboratory, advances other than the descriptive ones — and description is necessarily limited in scope — must be uncertain and irregular. In the present century the chief achievements have been in the experimental production of tumors, in their treatment with radiant energy and in the beginning of chemotherapy. Owing to refinements in technic, tumors of nearly all the viscera have become surgically accessible. Evidently, most of the major technical obstacles of the anatomy and physiology involved in the approach to cancer in whatever locus have been solved.

In the research laboratories remarkable strides have been made since 1900. Transplantable tumors have become available since the work of Jensen⁴⁶ in 1903, and a wide variety of tumors of chickens, rabbits, rodents and frogs have been discovered. The viruses have been seriously implicated in certain neoplasms, as first shown by Rous⁴⁷ in 1911. The production of cancer in the laboratory with pure chemicals has been achieved.⁴⁸ The endocrine basis and methods for the experimental production of breast cancer have been discovered.

The diagnosis of tumors by chemical means was mentioned above. This is the newest and a promising field in cancer research, and it is striving to fill a grave hiatus. The importance of chemical investigation of the activity of tumors is that they

provide a measure. The greatest handicap to research on cancer is the lack of a yardstick—something that can be measured at daily intervals. This can be done only for tumors of the blood-forming organs, for osteogenic sarcoma and for cancer of the prostate.

Another of the recent developments in cancer is the chemical treatment of neoplasms of epithelial and hemopoietic tissues. Some progress has been made in the chemotherapy of prostatic and breast cancer, in which improvement has been profound and prolonged in many cases. Remissions of advanced neoplasms are being produced by chemotherapy. Although the treatment of carcinoma by medicines has been exceedingly limited, enough progress has been made so that it may be predicted with confidence that the medical therapy of cancer will increase in the future.

Therefore, I can now approach the somewhat delicate question of the prognosis of the surgery of cancer, realizing that prognosis and prophecy bear a close relation. The technical accomplishments of the surgeons have been brilliant and splendid but only when the lesion is essentially localized. The inherent defect in the surgical method is the impossibility of removal of widespread neoplasms, and the prognosis for treatment by classic surgery in metastatic cancer is poor. Nothing, however, stands in the way of surgical research on neoplasia, and much information may be expected from the surgical laboratories.

The constantly expanding significance, for the advance of medicine, of the research laboratory conducted in connection with a surgical clinic has been repeatedly emphasized. Since the surgical departments at present have greatest access to and often the greatest interest in the clinical course of patients with cancer, it is essential that the surgical laboratory take the lead in converting the surgery of cancer into medical treatment—this self-effacement being in keeping with the great tradition of surgery.

Fortunately, the avenues of research provide unlimited scope for constructive thought, and the technics of surgery applied to research problems in cancer may be developed to a high state of intellectual polish. At the risk of sounding hortatory, I wish to say that it devolves on the surgeons to make more investigation of tumors in their broader aspects. The researches are not without interest, and the opportunity to contribute to medicine through participation in investigations on cancer is large, hence, the prognosis for the broad surgical discipline in cancer is excellent.

OBSERVATIONS ON A FAMILY EPIDEMIC OF INFECTIOUS HEPATITIS*

HENRY G. KUNKEL, M.D.,† and CHARLES L. HOAGLAND, M.D.‡

NEW YORK CITY

An epidemic of infectious hepatitis occurring in 9 of 10 children in a single family was followed for five months in New York City. Such a high incidence of the disease in a group is unique in itself; in addition, these cases offered special information on four separate aspects of the disease — namely, epidemiology, the comparative value of certain liver-function tests, the occurrence of spider angiomas in the acute stage of infectious hepatitis and the incidence of subicteric cases.

All members of the family were observed in the Outpatient Department of the Rockefeller Hospital where liver-function tests were performed at regular intervals; 3 were admitted to the hospital for special studies. Friends of the family who came in contact with the children were also observed; 2 of this group were hospitalized with infectious hepatitis. The chief source of information regarding the illness of the children was the mother of the family, a trained nurse familiar with liver disease.

Several descriptions of family epidemics of infectious hepatitis have appeared in the literature in recent years.¹⁻⁴ The mode of spread in these families was generally believed to be droplet infection. Recent work on human volunteers has shown that the disease can be transmitted experimentally to man by parenteral injection of small amounts of infective serum, by ingestion of infective serum or feces and by the spraying of infective feces into the nasopharyngeal passages.⁵⁻⁷

During an epidemic in a summer camp, Neefe and Stokes⁸ found the virus of infectious hepatitis in the drinking water. This work, together with that of others,^{9, 10} indicates that contaminated water may be the source of infection in certain epidemics. Milk and food have also been implicated in a few outbreaks.^{11, 12} A characteristic of epidemics begun by contaminated food or water is their explosive nature, although sporadic cases often followed. Most of the epidemics described in the literature, however, are characterized by the serial occurrence of cases over a period of several months with a history of contact between the majority of patients. Some-

times, the contact appeared to be slight, and this led to postulation of droplet and air-borne infection. In view of the recent comparatively easy transmission of the disease in human volunteers by infective fecal material, spread by contact now seems more probable. The family epidemic under consideration in this paper offers certain information on this subject.

Brief summaries of the case records are as follows:

CASE 1. On November 15, 1945, this 10-year-old girl developed nausea, vomiting, abdominal pain and fever. These symptoms persisted for 2 days and were followed by a period of anorexia that lasted for 1 week. Considerable fatigue was noted, and the patient was forced to stay out of school for 10 days. Recovery was rapid and except for a weight loss of 7 pounds the patient felt fine by November 20. No jaundice was noticed.

Physical examination on January 26 disclosed a definite spider angioma over the left shoulder that blanched well on pressure. The liver and spleen were not palpable or tender. Liver-function tests revealed no abnormalities. On March 26 there were no changes except that the spider angioma had decreased in size and no longer blanched on pressure. On August 8 the angioma had completely disappeared.

CASE 2. On November 19, 1945, this 8-year-old boy developed pain in the upper abdomen and a loss of appetite that persisted for 2 days. A definite tenderness in the upper right side of the abdomen was noted by his mother. He stayed out of school for 1 day. Several nosebleeds occurred at that time — these were the first that had ever been noted. Recovery was rapid, and there were no further complaints. No jaundice was noticed.

Liver-function tests on January 25 disclosed no abnormalities.

Physical examination on January 26 revealed that the liver and spleen were not palpable or tender. Two definite spider angiomas were visible, one on the neck and one on the left shoulder, one showed blanching on pressure. On March 25 no changes were noted, except that both spider angiomas were slightly less distinct, but they were still noticeable, neither showed blanching on pressure. Physical examination on August 8 showed two small red spots still visible at the site of the spider angiomas, they no longer had the shape of a spider and did not blanch on pressure.

CASE 3. On November 25, 1945, this 6-year-old boy developed a moderate diarrhea that was followed by considerable pain and tenderness in the right upper abdomen. Some nausea and anorexia were present but no vomiting. No jaundice was noticed. He recovered uneventfully except for slight pain over the liver area that persisted for several weeks. He stayed out of school for 5 days because of illness.

Physical examination on January 26, 1946, showed that the liver and spleen were not palpable or tender. Seven definite spider angiomas were found over the arms and shoulders, four of them blanched on pressure. Determinations of bromsulphalein retention and plasma bilirubin were normal. The thymol-turbidity values were as follows: on January 26,

*From the Hospital of the Rockefeller Institute for Medical Research.
†Assistant, Rockefeller Institute for Medical Research.
‡Deceased. Formerly member the Rockefeller Institute for Medical Research, and physician, Hospital of the Rockefeller Institute for Medical Research.

11 units, on February 20, 10 units, on March 25, 6 units, and on August 8, 4 units

On March 25 the liver and spleen were not palpable or tender. Five of the seven spider angiomas were still present, but they had faded considerably, only one blanched on pressure. On August 8 two small spider angiomas were still visible, one blanched on pressure. Red spots remained at the sites of two old spider angiomas.

CASE 4 On December 22, 1945, this 15-year-old boy developed nausea, anorexia and vomiting, which lasted for 2 days. He also complained of soreness over the abdomen and of nosebleeds. He continued to go to school, however. Recovery was uneventful except for persistent soreness over the abdomen that caused him to bend over slightly as he walked. No jaundice was noticed.

Physical examination on January 26, 1946, revealed the liver edge to be just palpable on deep inspiration and slightly tender. The spleen was not palpable. No spider angiomas were observed. The bromsulfalein retention and plasma bilirubin were normal.

On March 25 the liver and spleen were not palpable or tender, and there were no spider angiomas.

The thymol-turbidity values were as follows on January 26, 13 units, on February 20, 11 units, and on March 25, 5 units.

CASE 5 On January 12, 1946, this 17-year-old boy developed a headache associated with chills and fever. This was followed by nausea, anorexia and an episode of vomiting. The acute symptoms lasted approximately 1 week. Other symptoms included soreness over the liver area, hives, itching of the skin, marked fatigue, somnolence, clay-colored stools and a weight loss of 12 pounds. Jaundice was noticed on January 20, 4 days after the onset of dark urine. Recovery was uneventful except for liver tenderness, which persisted for approximately 3 weeks.

Physical examination on January 25 revealed the liver to be palpable two fingerbreadths below the costal margin and definitely tender. The spleen was not palpable. A definite spider angioma was noted over the anterior portion of the neck.

On March 25 the liver was not palpable or tender, and the spleen was not palpable. The spider angioma had almost disappeared but could still be found. On August 8 the spider angioma had completely disappeared.

The liver-function tests were as follows:

DATE	PLASMA BILIRUBIN	BROMSULFALGIN RETENTION AT 45 MINUTES	THYMOL TURBIDITY
	mg /100 cc	%	units
January 26	2.8	27.5	14
February 1	1.1	3.5	17
March 25	0.8	2.0	8
August 8	0.7	3.0	5

CASE 6 On January 20, 1946, this 12-year-old boy developed a slight loss of appetite and a feeling of malaise. Two days later jaundice was noticed, and he was admitted to the hospital. The jaundice was slight and rapidly disappeared. The liver and spleen were never palpable or tender, and no spider angiomas were observed. The patient made an uneventful recovery.

The liver-function tests were as follows:

DATE	PLASMA BILIRUBIN	BROMSULFALGIN RETENTION AT 45 MINUTES	THYMOL TURBIDITY
	mg /100 cc	%	units
January 24	3.5	46	14
January 30	3.0	37	19
February 6	0.9	6	18
February 17	0.6	3	10
April 23	—	—	3

CASE 7 On January 21, 1946, this 20-year-old girl developed nausea and anorexia associated with a mild fever. This was followed by moderate abdominal pain and a feeling of fatigue. Jaundice was noticed on January 25, and she was admitted to the hospital.

Physical examination disclosed marked liver tenderness, the liver was palpable three fingerbreadths below the costal margin. The spleen was also palpable. No spider angiomas were observed. The patient showed rapid improvement on

bed-rest therapy. The liver tenderness persisted for 2 weeks after admission. Recovery was uneventful.

The liver-function tests were as follows:

DATE	PLASMA BILIRUBIN	BROMSULFALGIN RETENTION AT 45 MINUTES	THYMOL TURBIDITY
	mg /100 cc	%	units
January 25	5.0	48	17
January 29	7.0	40	28
February 5	1.4	6.0	20
February 11	0.8	2.0	21.5
February 19	0.6	1.0	12.3
February 26	0.4	2.0	9.5
March 6	0.5	1.0	6.7
March 13	0.5	1.0	6.3
April 7	0.4	1.0	5.9
April 23	0.2	2.0	4.0

CASE 8 On January 24, 1946, the mother noticed that this 3-year-old girl had lost her appetite. The temperature was 101°F. On the following day the patient was seen at the hospital.

Physical examination revealed no evidence of jaundice. The liver and spleen were not palpable or tender. The temperature was 100°F. The patient regained her appetite 2 days later, and no further signs or symptoms were demonstrable.

The liver-function tests were as follows:

DATE	PLASMA BILIRUBIN	BROMSULFALGIN RETENTION AT 45 MINUTES	THYMOL TURBIDITY
	mg /100 cc	%	units
January 25	0.5	13.5	9.0
February 2	0.2	1.0	13.0
March 25	0.3	2.0	7.0
August 8	0.4	2.0	4.0

CASE 9 On February 8, 1946, this 13-year-old boy noticed a slightly sore throat. His mother found the temperature to be 104°F. The patient had a slight headache and a decrease in his appetite at this time but no nausea or vomiting. He was admitted to the hospital 24 hours after the onset of symptoms.

Physical examination showed that the liver and spleen were not palpable or tender. There were no spider angiomas and no icterus. The throat was somewhat reddened. A throat culture was negative. The temperature was 103°F but fell to normal 12 hours after admission. Anorexia persisted for 2 days. The liver and spleen never became palpable or tender. On February 10 the patient developed a large spider angioma on the right side of the neck that had not been present on admission and another small one over the right shoulder. These showed gradual fading over a 4-month period of observation. Careful observation also revealed a slight yellowing to the sclerae on February 15, which disappeared rapidly. Recovery was uneventful.

The liver-function tests were as follows:

DATE	PLASMA BILIRUBIN	BROMSULFALGIN RETENTION AT 45 MINUTES	THYMOL TURBIDITY	CEPHALIN FLOCCULATION
	mg /100 cc	%	units	
January 26	0.4	2.5	0.5	0
February 8	0.6	30.5	3.5	++
February 11	1.0	31.5	12.5	++
February 13	2.3	34.5	16.3	++
February 18	1.3	11.5	21.5	++
February 25	0.5	3.0	22.7	+++
March 5	0.6	1.2	15.5	++
March 12	0.4	2.0	13.5	++

EPIDEMIOLOGY

The origin of the outbreak was not completely certain. One member of the family (M. G.) had been stationed at a naval base in Virginia at a time when a number of cases of infectious hepatitis were occurring. Approximately a month prior to the first case in the family, he came home on five days' leave. During that time he became ill with symptoms of nausea, dizziness and fever, he remained in bed at home for three days. No jaundice was noticed by

his mother, and he returned to duty at the end of his visit feeling well. No further information could be obtained. In the light of later developments, it seems possible that he had a light attack of infectious hepatitis and transmitted it to other members of the family. No known cases of jaundice had occurred in the community in recent years prior to the first case in this family.

The sequence of events may best be followed by a division of the outbreak into six parts (Fig 1). In

tenement house. This consisted of a kitchen and bedroom connected by a hallway that was broken up into three small bedrooms (Fig 2). A small bathroom and toilet opened into the kitchen. The most striking feature of the apartment was the close proximity of the seven beds in the hallway and bedroom. Two children slept in each of four of the beds, and there was considerable variation in occupancy. The father worked at night and slept during the day in any bed that was not occupied when he returned

FIGURE 1 Time Relation of the Cases of Infectious Hepatitis in the Family G Epidemic

October M G, who was probably the origin of the epidemic, became ill at home while on leave from the Navy. In November, 3 siblings became ill. A month later a single case occurred in the family. In January, 4 new cases appeared in the family. And in February a single case occurred in the family and 2 cases appeared in friends of E G (Case 5).

This epidemic was not investigated until the beginning of the second outbreak in the family. The diagnosis of infectious hepatitis in the cases of the first outbreak was made on the basis of a characteristic symptomatology corroborated by at least one persistent finding, such as liver tenderness, spider angiomas or abnormalities in liver-function tests. In the other cases, which were followed throughout the course of the disease, the diagnosis was definite because of the presence of jaundice or marked aberrations in two or more liver-function tests. Six patients in the family did not show jaundice. Only 1 child and the parents demonstrated no evidence of the disease, although they were examined and tested on several occasions. This epidemic, therefore, represented 9 cases of infectious hepatitis among the children of the family and 2 cases among friends of one of the children.

The home conditions were inadequate for such a large family. The 10 children and their parents lived in a moderately small apartment in an East Side

tenement house. The sheets on the beds were changed every two weeks. Except for the crowded condition of the beds, conditions in the apartment were good. The children were kept clean, and the mother was careful with the food. The family was healthy, and no illnesses besides the usual childhood diseases had ever appeared.

Several epidemiologic studies on infectious hepatitis have been reported in which the spread of the disease was related to contact in sleeping quarters.¹²⁻¹⁵ In the outbreak under study, it is difficult to escape the conclusion that the crowded sleeping quarters were in some way responsible for the high incidence of cases.

An approximation of the length of the incubation period of the disease in this epidemic can be gathered from the fact that two friends of one patient (Case 5) developed the disease twenty-six and twenty-eight days respectively after he became ill. These friends had had no contact with any other members of the family and had not been near any other known cases of infectious hepatitis. They saw the patient only at a boys' club to which none of the other members of the family belonged, their contact was fairly close, and they admitted the possibility of an interchange of a single cigarette while the three of them together with several others, played pool. The patient attended the club during the night prior to the onset

of symptoms and then stayed away for two weeks because of illness, twenty-seven days is therefore the probable incubation period, although the possibility exists that he may have infected them several days prior to the onset of his own illness. The close relation in the time of occurrence in these 2 cases adds validity to the assumption of such an incubation period.

The 10 children of the family who were at home lived under conditions that required the closest contact. They all ate together around a very small

table to contract the disease from the 3 children with whom they lived every day during their illness in the November outbreak.

In January, 4 children developed infectious hepatitis over a period of twelve days — approximately a month after the single case in December. They must have contracted the disease from this patient who kept the infection alive in the family between the November and January outbreaks.

Finally, in February, another boy became ill with the disease. He must have obtained the virus from

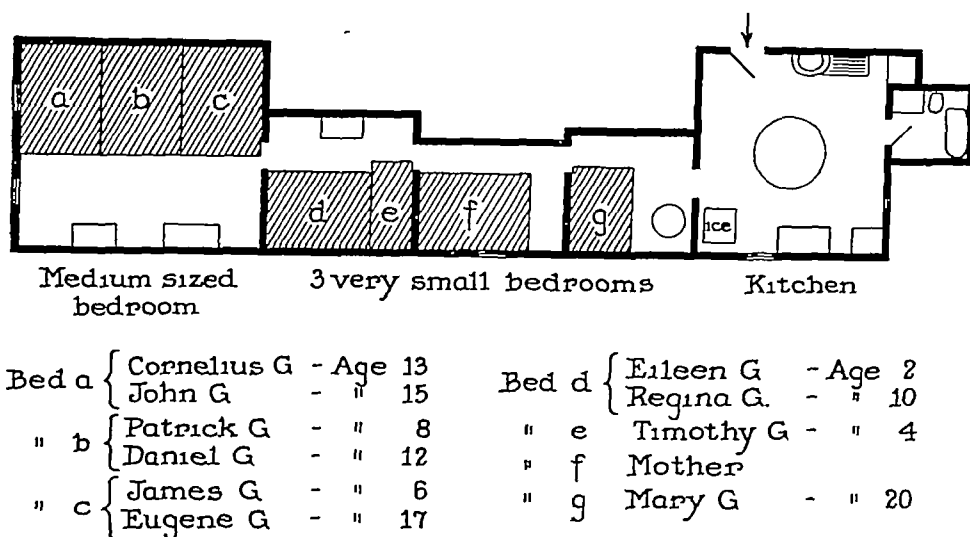

FIGURE 2 Plan of the Apartment of Family G

table, they all used the same small bathroom, and, under the crowded conditions that existed in the apartment, they practically all slept together. The older children washed and cared for the younger ones. It is to be expected that a contagious infection would spread with ease and rapidity through such a group. At least 9 of the children were susceptible to the disease, as shown by the fact that they eventually became ill. The infection, however, did not spread rapidly through the family. Three children became ill over a period of ten days in November. They probably contracted the disease from their sailor brother, who had been ill at home approximately a month earlier. Six susceptible children failed to develop the disease at that time, although they were in equally close contact with him.

In December, 29 days after the last case of the November outbreak, one boy developed the disease. He must have contracted the infection from one of the children of the November outbreak, if the incubation period is at all close to the estimated twenty-seven days. Five susceptible children failed

one of the January group after escaping three previous periods when others in his family had become infected.

One of the children apparently never contracted the disease, although he was exposed fully as much as the others in his family. The possibility remains however, that he had a subclinical infection.

The question why the parents did not come down with infectious hepatitis is a slightly different one. They were exposed to the virus in each of the outbreaks fully as much as the children. Neither gave a past history of jaundice. If they were as susceptible as the children, the chances would have been 100% that at least one of them would contract the disease. The lack of susceptibility to the disease of older people has frequently been noted. Immunity as a result of mild unnoticed infection with the disease earlier in life has been offered as a possible explanation.

This serial spread in families has been noted by Pickles² and Newman³ and is without counterpart in any other disease. That infectious hepatitis is not

extremely contagious is evident from this type of spread. The demonstration of subclinical infections, missed infections and carrier states adds strength to the idea that the disease is usually spread by contact. In the outbreak under consideration, only 5 of the 11 patients showed jaundice. Diagnosis of infectious hepatitis in 2 cases was made by means of liver-function tests alone in the absence of signs or symptoms characteristic of the disease, these are discussed below. There was definite evidence of the existence of cases that might have been missed under ordinary conditions. The chain of events in the

LIVER-FUNCTION TESTS

Following a study of various tests of liver function in acute hepatitis among Navy personnel at the Rockefeller Hospital, the conclusion was reached that the condition of the patient could best be evaluated by the determination of the plasma bilirubin, the bromsulfalein retention and the thymol turbidity.¹⁶ The use of these tests in the epidemic described above offered further information regarding their comparative significance and showed their value in the detection of cases without

FIGURE 3 Comparative Results on Serial Determinations of Plasma Bromsulfalein Retention, Plasma Bilirubin and the Thymol Turbidity Reaction of the Serum in Cornelius G (Case 9)

epidemic would not have been evident if sole reliance had been placed on the presence of jaundice. Recent studies on poliomyelitis have shown the presence of virus in the stools of people who have had close contact with the disease and who never showed evidence of infection. They undoubtedly act as carriers. This state of affairs has not as yet been demonstrated in infectious hepatitis, although the virus is present in the feces of certain patients suffering from the disease. One cannot help remarking that the epidemiology of the two diseases has many similarities. In the family under discussion the contact between the children was extremely close, and spread by fecal contamination seems likely. Mild cases of infectious hepatitis other than those found in this epidemic must exist, and these, together with probable carriers of the virus, may explain the apparent absence of contact between cases that has often been noted and used as an argument against contact as a significant agent in the spread of the disease.

jaundice. The thymol-turbidity test was found to have special use in the epidemiologic study. Figure 3 presents the results of serial determinations in Case 9. Because of illness in his siblings, this patient was examined ten days prior to the onset of his own illness, and normal values for the various liver-function tests were found. This gave added significance to the changes produced when the disease began. It can be seen that the bromsulfalein retention became elevated within twenty-four hours after the onset of the first symptoms. Values for the plasma bilirubin did not begin to rise until the fifth day, reaching a peak on the seventh day of the disease. This peak corresponded with that of the bromsulfalein retention, and values for the two tests rapidly returned to the normal range. The curve of serial determination of the thymol-turbidity test, however, showed a delayed rise reaching a peak on the nineteenth day of the disease at a time when the other two tests had fallen to normal and the patient was free of symptoms. The thymol-turbidity values

then fell slowly, reaching the normal range on approximately the nineteenth day of the disease.

The other cases in the family that were studied also bore out the findings that the bromsulfalein retention demonstrates an immediate increase with the onset of symptoms during the preicteric stage and that the thymol-turbidity values show a delayed rise and prolonged elevation persisting well after the end of all symptoms of the disease.

Despite these marked abnormalities in liver-function tests the patient in Case 9 had only minor symptoms, consisting of mild anorexia, sore throat and slight fatigue. No definite jaundice was ever visible, and it was only by extremely careful observation that a slight yellow tinge was observed in the scleras on one day. There were none of the signs or symptoms diagnostic of infectious hepatitis. This case would have been missed if the sensitive liver-function tests described above had not been applied.

The value of these tests as diagnostic aids was also demonstrated in Case 8. This three-year-old girl developed a loss of appetite, which was reported by her mother only because the slightest signs of illness were looked for following the illness of several of the other children. On the following day the bromsulfalein test showed 12.5 per cent retention of the dye, and the thymol-turbidity value was 9 units. Subsequently, the thymol-turbidity values rose to a peak of 13 units and then slowly fell to normal, and the bromsulfalein retention remained within the normal range. The patient developed no further symptoms, the liver was never palpable or tender, and there was no jaundice or elevation of the plasma bilirubin. The pattern in this case was similar to that in Case 9, with an immediate rise and rapid fall of the bromsulfalein retention associated with a delayed rise and prolonged elevation of the thymol reactivity of the serum. The combination of these tests made possible the diagnosis of an extremely mild case of infectious hepatitis.

Several members of the family were seen just after the symptoms of infectious hepatitis had subsided, when the plasma bilirubin and bromsulfalein retention were normal. The thymol-turbidity test, however, still revealed elevated values that fell slowly to normal over a period of several weeks. The use of this test made it possible to confirm the diagnosis of infectious hepatitis after the patients had apparently recovered from the disease. The patient in Case 3 illustrates this point. He developed nausea, anorexia, pain over the liver area and diarrhea lasting for three days. Moderate fatigue and liver pain persisted for several weeks. No jaundice was noted. When he was first seen two months after the onset, he had no complaints, and physical examination was negative. Determinations of plasma bilirubin and bromsulfalein retention were normal. The thymol reactivity of the serum was still positive at 11 units, and this gradually fell to 4 over a period of several months. The symptoms of the acute at-

tack were characteristic of infectious hepatitis, and the thymol-turbidity test confirmed the diagnosis. Thus, it can be seen that this test is of value in an epidemiologic study not only because of its aid in the diagnosis of nonicteric cases but also because it remains positive for such a long period, revealing significant data after other evidences of the disease have disappeared.

OCCURRENCE OF SPIDER ANGIOMAS

Spider angiomas in the acute stage of infectious hepatitis have occasionally been described,^{17, 18} but little emphasis has been placed on their occurrence. Most clinical descriptions of the disease do not even list them among the physical signs. In a clinical study of Navy patients at the Rockefeller Hospital, approximately 30 per cent developed spider angiomas during the acute stage of the disease.¹⁹ The incidence was much higher among patients with chronic hepatitis, and new spider angiomas usually signified a poor prognosis when they developed after the acute stage of the disease. They have served as a useful physical sign for following the transition from acute to chronic infectious hepatitis.

In the epidemic under discussion 5 children showed definite spider angiomas, and their presence aided in confirming the diagnosis of the disease in some of the cases without jaundice. Case 9 offered a good opportunity to study the formation and disappearance of the angiomas. The patient was examined ten days before the illness, and a search was made for spider angiomas because of their presence in his siblings; none were found. Twenty hours after the onset of the first symptoms he was again examined, and none were found. On the following day, however, he was discovered to have developed during the night a large angioma located over the lower right side of the neck and a considerably smaller one on the right shoulder, both blanched readily on pressure. They were carefully observed for a six-month period, during which a gradual fading took place. During the second month the quality of blanching on pressure disappeared. At the end of six months, the smaller one had completely disappeared, and the larger was visible only as a small, barely discernible, red speck. These marks, however, could still be identified as spider angiomas at the end of four months, long after the illness had terminated.

In Case 3 seven definite spider angiomas developed over the arms and shoulders. The mother noticed their appearance at the time of the acute symptoms, and the angiomas were still present when the patient was first seen in the clinic two months later. They stood out more plainly against the background of his smooth, white skin than they would have in an adult. These spider angiomas faded slowly, and two could still be identified at the end of eight months, although the patient had no persistence of signs or

symptoms of the disease. Their presence confirmed the diagnosis of infectious hepatitis.

Next to liver tenderness spider angiomas proved to be the most useful physical sign in the study of the cases in this epidemic. They were of special value in the patients whose illnesses had begun before the investigation and in whom the diagnosis was not definite from the description of the acute symptoms. Their long persistence following a short, mild attack of infectious hepatitis was somewhat unexpected. It suggests the possibility that the so-called "spontaneous spider angiomas" in normal persons occasionally result from a mild attack of infectious hepatitis without jaundice. In this group of children 4 of the 5 cases showing spider angiomas were so mild that jaundice was not seen. Another point that should be raised is that the persistence of the angiomas could not be explained on the basis of a lingering hepatitis. These children all recovered rapidly and uneventfully from the acute attack. The significance of persistent spider angiomas in chronic hepatitis and cirrhosis should be evaluated in the light of these findings.

INCIDENCE OF INFECTIOUS HEPATITIS WITHOUT JAUNDICE

The existence of nonicteric cases of infectious hepatitis is now clearly recognized, but there is no agreement about the number of such cases. Various estimates for the percentage of nonicteric cases have been given: 9 per cent (Bates²⁰), 50 per cent (Barker et al.²¹), 27 per cent (Neefe and Stokes⁸), 22 per cent (Hardy and Feemster²²), and 89 per cent (Gowen²³). Undoubtedly, the percentages vary with the epidemics. A possible reason for the marked divergence noted is that each group of patients was studied in a different manner. The high incidence obtained by Gowen²³ in Tunisia is due to the fact that he estimated the icteric index in a large number of persons and considered an abnormal value as in-

The mildest case occurred in Case 8, in which the patient was the youngest of the family, and the severest case occurred in the oldest patient (Case 7). Table 1 presents the age distribution in relation to the occurrence of jaundice, and it is evident that jaundice occurred more frequently in the older age group.

SUMMARY

The serial occurrence over a period of five months of 9 cases of infectious hepatitis in a single family is described.

Contact was found to be the probable mode of spread in this outbreak.

Determinations of bromsulfalein retention and thymol reactivity of the serum proved to be valuable aids in the detection of nonicteric cases.

The thymol-turbidity test, because of its prolonged elevation, was of special value in an epidemiologic study.

Spider angiomas, which developed during the acute attack of infectious hepatitis, were found in 5 cases. The sudden onset and delayed disappearance of this physical sign are described. It proved to be helpful in corroborating the diagnosis in 2 cases.

Six children did not develop clinical evidence of jaundice.

The severity of the illness and the presence of jaundice showed a definite relation to the age of the children, the disease being milder in the younger group.

dicative of a case of infectious hepatitis. The lack of corroborative evidence opens his findings to some question. In the family epidemic reported above 6 children had infectious hepatitis without jaundice—an incidence of 66 per cent.

Age seemed to be an important factor in the determination of the severity of the illness and the presence of jaundice in the members of this family.

then fell slowly, reaching the normal range on approximately the nineteenth day of the disease

The other cases in the family that were studied also bore out the findings that the bromsulfalein retention demonstrates an immediate increase with the onset of symptoms during the preicteric stage and that the thymol-turbidity values show a delayed rise and prolonged elevation persisting well after the end of all symptoms of the disease

Despite these marked abnormalities in liver-function tests the patient in Case 9 had only minor symptoms, consisting of mild anorexia, sore throat and slight fatigue. No definite jaundice was ever visible, and it was only by extremely careful observation that a slight yellow tinge was observed in the scleras on one day. There were none of the signs or symptoms diagnostic of infectious hepatitis. This case would have been missed if the sensitive liver-function tests described above had not been applied.

The value of these tests as diagnostic aids was also demonstrated in Case 8. This three-year-old girl developed a loss of appetite, which was reported by her mother only because the slightest signs of illness were looked for following the illness of several of the other children. On the following day the bromsulfalein test showed 12.5 per cent retention of the dye, and the thymol-turbidity value was 9 units. Subsequently, the thymol-turbidity values rose to a peak of 13 units and then slowly fell to normal, and the bromsulfalein retention remained within the normal range. The patient developed no further symptoms, the liver was never palpable or tender, and there was no jaundice or elevation of the plasma bilirubin. The pattern in this case was similar to that in Case 9, with an immediate rise and rapid fall of the bromsulfalein retention associated with a delayed rise and prolonged elevation of the thymol reactivity of the serum. The combination of these tests made possible the diagnosis of an extremely mild case of infectious hepatitis.

Several members of the family were seen just after the symptoms of infectious hepatitis had subsided, when the plasma bilirubin and bromsulfalein retention were normal. The thymol-turbidity test, however, still revealed elevated values that fell slowly to normal over a period of several weeks. The use of this test made it possible to confirm the diagnosis of infectious hepatitis after the patients had apparently recovered from the disease. The patient in Case 3 illustrates this point. He developed nausea, anorexia, pain over the liver area and diarrhea lasting for three days. Moderate fatigue and liver pain persisted for several weeks. No jaundice was noted. When he was first seen two months after the onset, he had no complaints, and physical examination was negative. Determinations of plasma bilirubin and bromsulfalein retention were normal. The thymol reactivity of the serum was still positive at 11 units, and this gradually fell to 4 over a period of several months. The symptoms of the acute at-

tack were characteristic of infectious hepatitis, and the thymol-turbidity test confirmed the diagnosis. Thus, it can be seen that this test is of value in an epidemiologic study not only because of its aid in the diagnosis of nonicteric cases but also because it remains positive for such a long period, revealing significant data after other evidences of the disease have disappeared.

OCCURRENCE OF SPIDER ANGIOMAS

Spider angiomas in the acute stage of infectious hepatitis have occasionally been described,^{17, 18} but little emphasis has been placed on their occurrence. Most clinical descriptions of the disease do not even list them among the physical signs. In a clinical study of Navy patients at the Rockefeller Hospital, approximately 30 per cent developed spider angiomas during the acute stage of the disease.¹⁹ The incidence was much higher among patients with chronic hepatitis, and new spider angiomas usually signified a poor prognosis when they developed after the acute stage of the disease. They have served as a useful physical sign for following the transition from acute to chronic infectious hepatitis.

In the epidemic under discussion 5 children showed definite spider angiomas, and their presence aided in confirming the diagnosis of the disease in some of the cases without jaundice. Case 9 offered a good opportunity to study the formation and disappearance of the angiomas. The patient was examined ten days before the illness, and a search was made for spider angiomas because of their presence in his siblings, none were found. Twenty hours after the onset of the first symptoms he was again examined, and none were found. On the following day, however, he was discovered to have developed during the night a large angioma located over the lower right side of the neck and a considerably smaller one on the right shoulder, both blanched readily on pressure. They were carefully observed for a six-month period, during which a gradual fading took place. During the second month the quality of blanching on pressure disappeared. At the end of six months, the smaller one had completely disappeared, and the larger was visible only as a small, barely discernible, red speck. These marks, however, could still be identified as spider angiomas at the end of four months, long after the illness had terminated.

In Case 3 seven definite spider angiomas developed over the arms and shoulders. The mother noticed their appearance at the time of the acute symptoms, and the angiomas were still present when the patient was first seen in the clinic two months later. They stood out more plainly against the background of his smooth, white skin than they would have in an adult. These spider angiomas faded slowly, and two could still be identified at the end of eight months, although the patient had no persistence of signs or

meat-free diet, and the patient was asymptomatic. Further x-ray studies of the esophagus, stomach and small bowel revealed no abnormality.

DISCUSSION

The possible relation of the bleeding to the exposure to low pressure is interesting. The character of the bleeding was such that it resembled a slow oozing over a period of nearly a week — it was not the sudden rush and exsanguination typical of a bleeding ulcer. It could be said that the relation of this bleeding to the exposure to low pressure was purely fortuitous. The short time between the two events is a persuasive reason for believing that the bleeding was the result of the exposure to the low pressure. In addition, the association of the abnormally severe crampy abdominal pains with the exposure to low pressure is another reason for considering the bleeding related to the latter event. The patient had had an uneventful simulated flight nine months previously to 39,000 feet for thirty minutes. Ordinarily, some abdominal distention and slight abdominal cramps can be expected on exposure to low pressure, but the symptoms were severer and associated with an inability to pass flatus, which ordinarily relieves the mild abdominal distress.

Gas saturated with moisture and at a constant temperature can be calculated to expand about six and a half times under the conditions that the patient experienced. Because of the reduction in the partial pressure of oxygen, the breathing of 100 per cent oxygen at 33,700 feet is comparable to the breathing of air at sea level. At 41,000 feet, in spite of the breathing of 100 per cent oxygen, experiments at the Aeromedical Laboratory at Wright Field showed that the blood is approximately 85 per cent saturated with oxygen. This slight anoxic state may be enough to increase the effects of any trauma to capillary blood vessels.

During the course of the war, many men were processed in low-pressure chambers. The Air Surgeon's Office reports that 470,592 simulated altitude flights were made, ordinarily including 3 flights per person, and that during the course of the flights only 6 fatal cases traceable to this experience occurred.¹

It is not the intent of this paper to discuss the reasons for these fatalities. But a brief review of the autopsy protocols in 2 cases may be of interest. The subjects showed pulmonary edema, which appeared on the average about four hours after exposure and was the immediate cause of death. None of the patients gave a history of allergy. Two patients showed gross and microscopical hemorrhage into the gastrointestinal tract.

CASE 4. This officer had been exposed to a simulated altitude of 30,000 feet for 1 hour. Post-mortem examination showed the serous surface of the entire gastrointestinal tract to be smooth and free of exudate. The serosal vessels appeared congested. No subserosal hemorrhages were seen. The stomach contained about 200 cc of brownish fluid. Scat-

tered over the mucosa of the stomach and duodenum were numerous areas of hemorrhage. These were dark red and appeared to be of recent origin. They measured from 0.3 to 3 cm in diameter. The first 90 cm of the jejunum appeared normal. The mucosa of the remaining portion of the jejunum and all except the terminal 60 cm of ileum showed what appeared to be a diffuse confluent hemorrhagic necrosis. The mucosa was dark red. The lumen of the small intestine contained a moderate amount of reddish-black fluid. The small and large intestines were not distended. The mucosa of the colon showed no lesions. The lumen of the colon contained a moderate amount of yellow, soft fecal material. The appendix was not abnormal.

Microscopical examination revealed marked mucosal hemorrhage of the stomach and small intestine. The mucosa of the stomach showed slight autolytic changes, no other pathologic changes were noted. The mucosa of the duodenum had undergone slight autolysis. A section of mucosa from the small intestine disclosed some autolytic changes. One section from the site of hemorrhage showed the villi to be hemorrhagic, and blood cells were scattered throughout the connective tissue. The mucosa was covered with material consisting of red cells. The mucosa of the colon was intact, and only minimal pathologic changes were seen.

The anatomic diagnoses were acute pulmonary edema, pleural effusion and extensive capillary damage to the mucosa of the stomach and small intestine.

CASE 5. A private had been exposed to an altitude of 30,000 feet for 30 minutes. Post-mortem examination revealed no abnormalities in the stomach. The small bowel showed prominence of Peyer's patches in the vicinity of the ileocecal valve and 45 cm proximal to it. Scattered hemorrhagic streaks were observed throughout the small bowel, especially in the duodenum and the jejunal area.

The anatomic diagnoses were laceration of the dura and herniation of the brain (left parietal lobe), with congestion and edema of the brain tissues, marked pulmonary edema and extensive congestion of both lungs and scattered hemorrhages in the small intestine.

Two possibilities exist to explain the hemorrhages. The first is that the morphologic changes were a result of the profound shock that accompanied the fatal cases. Erlanger and his associates² and later Moon³ described the distinctive circulatory changes in shock that correspond to the gross and microscopical picture presented in these fatal cases.

The second possibility, which is theoretically plausible, is that air emboli developed in the distended capillary network of the bowel where the circulation was impeded. The mechanical distention from the formation of air emboli caused disruption and increased permeability of the capillary endothelium. It does not seem likely that the slight systemic anoxia, which was undoubtedly present in the case presented above, was in itself sufficient to cause hemorrhage, but conditions in the bowel may have aggravated the local anoxia that was present.

This first possibility may well apply to the fatal cases but not to the case reported above, for at no time did the patient give evidence of being in shock. It can safely be assumed that the bleeding in that patient was below the level of the pylorus, for it is infrequent that a gastric lesion is not associated with hematemesis.

Inquiries addressed to the Committee on Medical Research of the Office of Scientific Research and Development led to a reply from Dr. Kenneth B. Turner,⁴ chief of the Record Section, who did not recall having heard of a previous example of mas-

MASSIVE GASTROINTESTINAL BLEEDING FOLLOWING EXPOSURE TO LOW PRESSURE

W WILSON SCHIER, M D *

BOSTON

IN recent years reports of gastrointestinal hemorrhage from obscure and comparatively rare origins have been accumulating. Hematemesis is an exceedingly dramatic episode for the patient, and melena is equally so for the physician. After gastric or duodenal ulcer, varicosities of the esophagus and rectum or carcinoma of the stomach and large bowel have been dismissed, a diagnostic impasse is reached. This paper is the result of such a situation. No attempt is made to present an inclusive differential diagnostic study, but the possibilities of various lesions of more infrequent occurrence are considered. McBurney has been quoted as saying, "Deliver me from the man of one case." Nevertheless, the following single case report is presented as a diagnostic problem.

CASE REPORT

On October 2, 1943, a 29-year-old medical officer was admitted to a station hospital because of bloody diarrhea of 2 days' duration.

The past history was not remarkable except for a strong family and personal history of allergy. On one occasion 4 months previously, the patient had noted several purpuric spots on the forearms preceding a flareup of chronic neurodermatitis. In 1942 a tonsillectomy and adenectomy had been done without complication. A system review was non-contributory.

Two days before admission the patient had been exposed to a simulated altitude of 41,000 feet while demonstrating some of the phenomena of high-altitude physiology. He had felt well before entering the low-pressure chamber where this demonstration had taken place and had taken no medication except for 0.25 per cent Neosynephrine nose drops to alleviate symptoms of hay fever and to prevent aero-otitis. In addition, he had drunk a bottle of Coca-Cola before entering the chamber.

In a period of 20 minutes, pressure in the chamber was reduced from that of the ground level, approximately 12 pounds per square inch, — equivalent to 4280 feet above sea level, — to 2.6 pounds per square inch — equivalent to an altitude of 41,000 feet. During the reduction in pressure, the patient had crampy abdominal pain with distention. This was mild at first but increased during the 10 minutes at that pressure. The pressure was then increased to 2.75 pounds per square inch — equivalent to an altitude of 39,000 feet. This was maintained for ½ hour. The abdominal pain was not disabling but was definitely uncomfortable. It was relieved on return to ground-level pressure, the transition occupying 15 minutes, at that time the patient felt well. The abdominal pain disappeared during the increase in pressure.

He ate a good supper and went to bed early and to sleep quickly. About 4 hours after retiring he was awakened with crampy abdominal pains that were generalized and associated with a desire to evacuate. A large bloody diarrhea containing dark clots ensued. Three hours later similar rectal bleeding occurred. The next day the patient felt well and went about his daily duties. Three more stools, however, in the next 24 hours, more formed in character but tarry, brought him to the hospital.

The chief complaint on admission was a feeling of fatigue and muscular weakness. Physical examination was negative

except for pallor of the skin, congestion of the nose and a tarry stool on rectal examination.

The temperature was 98.6°F, the pulse 92, and the blood pressure 124/78.

Examination of the blood revealed a red-cell count of 4,300,000, with a hemoglobin of 13 gm, during the day the red-cell count fell to 3,500,000, with a hemoglobin of 12 gm. (On the day before admission, the red-cell count had been 5,070,000.) The nonprotein nitrogen was 32 mg and the blood sugar 115 mg per 100 cc, and a blood Kahn test was negative. The urine was a clear amber, with a specific gravity of 1.026, negative for albumin and glucose and microscopically normal.

On the 2nd day the patient felt better in the morning. The blood pressure was 122/78, and the pulse 90, the abdomen was soft without masses or tenderness. Toward evening the abdomen became distended, and the oral temperature rose to 99.0°F, and the pulse to 142. The red-cell count was 3,080,000, with 9 gm of hemoglobin and abundant platelets. The bleeding time was 90 seconds, and the clotting time (capillary tube) 45 seconds, the tourniquet test was negative. The white-cell count was 8200, with 70 per cent segmented and 2 per cent nonsegmented neutrophils, 24 per cent lymphocytes, 2 per cent monocytes, 2 per cent basophils and no eosinophils. A transfusion of 400 cc of Type A citrated blood was given without reaction.

On the 3rd hospital day the stools were reported negative for ova and parasites and nonlactose fermenting bacteria. The abdomen was less distended, the skin was pale, and the patient was comfortable but feeling much more lassitude. The diet was a modified Meulengracht regime with feedings of puréed food every 2 hours. The appetite was poor. Amphojel and lime water were given between feedings. That evening a 600-cc transfusion was given without reaction. The temperature had been rising throughout the day and had reached 103°F before the transfusion was begun. It fell slowly to normal in the next 36 hours and was accompanied by a fall in pulse.

On the 5th hospital day the stools became normal in appearance but remained guaiac positive. The patient was given a normal diet at that time.

On October 11 a proctoscope was introduced to its full distance of 25 cm without difficulty. The mucosa of the sigmoid and rectum appeared entirely normal. There were no tumors or areas of ulceration and no bleeding points. A small internal hemorrhoid was not believed to account for the bleeding.

On October 12 preliminary fluoroscopy of the chest was entirely negative. Examination of the large bowel showed no evidence of intrinsic organic disease. The terminal ileum filled and appeared normal, the appendix was partially filled. X-ray films made with the colon filled and after the evacuation of the barium, as well as contrast films after evacuation, failed to demonstrate any lesion within the large bowel.

On the following day preliminary chest fluoroscopy was again entirely negative. The esophagus was normal. The stomach was hyperactive, with deep regular peristaltic waves and rapid gastric emptying. The duodenal cap filled out well and showed no defects and no evidence of irritability. The duodenal loop appeared normal. Serial films of the small bowel made at hourly intervals disclosed no abnormality in the distribution of the barium meal.

On October 15 the patient was placed on a meat-free diet for 48 hours. The stools gave a ++ guaiac reaction but were guaiac negative 2 days later, when the patient was discharged. Examination of the blood at that time showed a red-cell count of 4,000,000, with 12 gm of hemoglobin. The patient was given a month's sick leave before resuming his regular duties and advised to continue amphojel, to avoid strenuous exercise and to have an x-ray checkup examination on return to duty.

One month after admission careful x-ray examination of the esophagus, stomach and duodenum was negative. Eighteen months later the stools were negative for occult blood on a

ATTITUDES TOWARD INFANT CARE

The care of infants is largely influenced by physiologic and psychiatric knowledge, much of which has accumulated in the past few years. Fundamental in this care are the notion that healthy newborn infants are physiologically equipped for survival in the environment into which they are born and, secondly, the certainty that, for the building up of a healthy new personality, a firm and comfortable relation between the infant and its mother is essential.

A suitable environment presupposes a mother or mother's substitute whose main concern is the welfare of the baby. She should be one person over a long period, since changing or competing persons make the proper emotional relation difficult. The second vital factor in the environment is food adequate in amount and suitable in quality. Protection from exposure and infection, which is also necessary, has already been discussed.

Introduced into such an environment, the baby has first of all an innate impulse to grow and develop. Growth varies tremendously in its intensity. Some well nourished babies weigh 17 or 18 pounds at the age of a year, whereas others weigh 10 pounds more at the same age. Running parallel to the impulse to grow are the senses of hunger, appetite and satiety, which govern much more accurately than any table of calories and ounces the amount of food needed and the frequency of its need. Food forced beyond the requirement indicated by instincts results in no increase in growth.

The impulse toward maturation of the nervous system is as inherent and characteristic as the growth impulse. It can be slowed only by major disasters and probably cannot be hastened by any method of training or feeding. The newborn has not the necessary intellectual equipment to learn by conditioning or teaching, and only begins to develop this faculty during the latter half of the first year. At birth, voluntary movement hardly exists, and years are required for its elaboration and perfection, the lateral tracts of the spinal cord remain only partially myelinated well into the second year. The differentiation between sleeping and waking, apart from the stimulus of hunger, is gradually developed in early infancy.

Emotional needs also tend to mature during infancy, but it appears that for an infantile emotional need to atrophy it must have been amply satisfied at some time. The most urgent infantile emotion seems to be the need for personal attachment to one person. Sucking, mouthing, smelling and feeling all appear to give a sense of emotional relaxation to infants, and many babies become irritable if deprived of them before they are outgrown. It may be that wetting and soiling are similarly satisfying in early infancy. Whether head banging, bedrocking and similar rhythmic motions are to be regarded as normal satisfactions or as evidences of pathologic emotional tensions is dubious, since such habits tend to appear in emotionally tense or defective infants.

Granted these hints regarding a point of view, what are the practical applications? So-called "demand feeding" is one of the most widely discussed issues at present. The notion is to feed the baby when he is hungry and cries for food. Such a schedule is often irregular during the first few days or weeks and is difficult to administer in the average lying-in hospital. Fortunately, most infants seem

sive intestinal bleeding following exposure to low pressure

Dr John F. Fulton,⁵ chairman of the Subcommittee on Decompression Sickness, National Research Council, reported that he had observed no cases of gross hemorrhage following exposure to high altitudes

Causes to be considered other than anoxia and distention are a Meckel's diverticulum, allergy and primary tumor of the small intestine

In 1808 Willan in his book *Cutaneous Disease* mentioned the relation of anasarctous lesions of the thighs and hands, presumable angioneurotic edema, associated with purpura, vomiting, abdominal pain, diarrhea and bloody stools. This was described more fully by Henoch in 1874, and the symptom complex was given his name. Sir William Osler⁶ presented several cases of purpuric and sometimes merely erythematous skin lesions associated with visceral lesions, particularly gastrointestinal bleeding.

The allergic background in the case presented above makes Henoch's purpura a possibility, but the single occurrence of bleeding and the older age group make this possibility less probable. An adequate follow-up study was not possible for the full evaluation of other possibilities. Esophagoscopy and gastroscopy might have been helpful. Early x-ray films would have been desirable after this massive gastrointestinal hemorrhage, and postponement of such examination may be the reason why no lesion was found.

Cases of undiagnosed gastrointestinal bleeding are common to the experience of every doctor, but not frequent enough for generalization from his personal experience. Stone⁷ presented 72 cases of massive melena of obscure origin, in 31 of which no cause could be ascribed, 6 of these patients were subjected to celiotomy—one on two occasions—without further elucidation of the etiology. Even at post-mortem examination of subjects with cirrhosis of the liver, esophageal varices are often demonstrated only with great difficulty although death followed sudden hematemesis.

Congenital diseases must be considered as causes of intestinal bleeding. Autopsy studies reveal that Meckel's diverticulum occurs in about 2 per cent of the population and three times as often in males as in females. The diverticula often contain heterotopic gastric mucosa or pancreatic tissue that is subject to ulceration.^{8,9} The symptoms often simulate peptic ulcer both in periodicity of pain and in bleeding. X-ray films of the small intestine do not contribute definitive information, and in the presence of questionable roentgenographic findings, a presumptive diagnosis of peptic ulcer is often made. The failure of x-ray examination to outline Meckel's diverticula is probably a result of their usual structure. Typically, the orifice is relatively large with a small lumen. The diverticulum is short,

consequently, barium enters easily and leaves promptly. In addition, overlying masses of small bowel may obscure diverticula that do remain filled. In fact, x-ray visualization is considered something of an achievement.¹⁰

Primary tumors of the small intestine are rare but are frequently associated with bleeding, intussusception and pain. Rankin and Mayo¹¹ list 31 cases of small-bowel carcinoma seen during the same interval in which 2646 cases of cancer of the stomach and 2775 of the large bowel and rectum were seen. Klingenstein¹² describes 2 cases of benign lesions of the small intestine complicated by severe hemorrhage. Benign tumors occur about half as frequently as the malignant variety. Segal, Scott and Watson¹³ presented a case of carcinoma of the jejunum in which the patient exsanguinated to a hemoglobin level of 6 gm. The carcinoma was a 3-mm nodule in the center of which was an area of ulceration. In the case presented above tumor seems unlikely because bleeding has not recurred in nearly three years.

In cases of massive gastrointestinal hemorrhage treatment for the loss of blood is, of course, of paramount importance. Early x-ray study seems advisable if the roentgenologist is cautioned to avoid kneading the abdomen. Under these circumstances, there can be little objection to x-ray examination except when the possibility of intestinal obstruction is present. Esophagoscopy and gastroscopy are recommended as part of the complete examination. Blood studies to eliminate certain purpuras as etiologic factors are necessary.

Stone⁷ emphasizes the fact that premature surgery should be avoided. It is quite possible that patients who have bled only once will bleed no more. When the source of bleeding is definite, surgery is indicated. In the cases that seem completely unexplained and in which the hemorrhages are severe and recurrent, operation is the recourse of desperation and bafflement. Such intervention may fail to discover or to relieve the difficulty.

SUMMARY

A case of severe intestinal hemorrhage associated with exposure to low pressure during simulated high-altitude flight is presented. The differential diagnoses are discussed, and possible etiologic factors reviewed—namely, shock, acute dilatation and air embolism of the bowel and increased capillary permeability associated with an allergic diathesis.

Other possible sources of bleeding of an obscure nature are discussed, including Meckel's diverticulum and new growths of the small intestine.

Treatment is symptomatic, with early transfusion. After the bleeding has been controlled, diagnostic procedures can be considered. Surgery is indicated when the source of the bleeding is definite and the lesion is remediable by surgery or when severe

These illustrations are, of course, isolated items from the life history of any child. They are presented in the hope of illustrating the point of view that, given time to mature appropriately before being asked to assume various responsibilities, each child will grow up able to utilize his innate abilities. A baby so handled has the satisfaction of developing new abilities and new aptitudes as a result of his innate endowment, rather than the frustration of having them imposed on him by a system that he neither understands nor desires. Pressure to learn early, constant training and strict discipline may tend to modify these abilities in a downward direction by producing a habit of resistance, frustration and anxiety. Finally, the resilience of the human infant and child must be recognized, for many able adults appear to have been most unwisely handled in childhood.⁶⁵⁻⁶⁹

DIAGNOSIS AND MANAGEMENT OF SEIZURES

This subject is particularly pertinent for pediatricians, because the younger the animal organism (whether human or subhuman) the greater the susceptibility to seizures, whether these are "spontaneous" or induced by a convulsant drug or fever. Each year the magazine *Epilepsia* reviews approximately two hundred and fifty articles that deal with the subject of convulsions or epilepsy. Yet only two or three articles in a hundred have appeared in a journal devoted to pediatrics. The brevity of the present review emphasizes the apathy of pediatricians toward this important and interesting disease.

Differentiation of the causes of seizures calls for detailed and co-ordinated study of patients with the co-operation of geneticists, obstetricians, pathologists and social therapists and with the aid of laboratory technics, particularly the electroencephalograph. A commendable effort in this direction is the long-term study of 800 epileptic patients at the Harriet Lane Hospital in Baltimore.⁷⁰ In 10 per cent of these patients the first convulsion occurred during fever. The prognosis proved to be better when there was a family history of childhood convulsions than if there was none. A report of book length is promised of the neurologic, physiologic and social pathology disclosed by this study.⁷¹ An interesting tabulation of the incidence of convulsions in 1543 children with various pathologic conditions has been made by Crump.⁷² For example, convulsions occurred in 7 per cent of patients with extracranial infections, in 55 per cent with meningitis, in 41 per cent with brain tumor, in 39 per cent with encephalitis and in 10 per cent with head and birth injuries. Among 1330 institutionalized patients reviewed by Yannet⁷³ there were 52 essential (genetic) epileptic patients (3.9 per cent). In addition there were 190 patients (14.2 per cent) with convulsive disorders. In the latter group, cerebral palsy, trauma and infections were most important. Also,

the incidence of convulsive disorders was directly related to the severity of the mental defect. A practical and useful discussion of various aspects of epilepsy in childhood is presented by Buchanan.⁷⁴

Fresh contributions to the management of epilepsy have been limited to new anti-seizure drugs. Of these, the preparation of greatest interest to the pediatrician is one that seems to be of specific value in the control of the petit-mal triad. These attacks are frequently repeated transient blackouts, myoclonic jerks or akinetic seizures. Up to now they have resisted drug therapy. Experience has conclusively demonstrated the effectiveness of Tridione (3,5,5-trimethyl oxazolidine-2,4-dione) in controlling seizures of the triad.⁷⁵⁻⁷⁶ Contrary to the reports of others,⁷⁷⁻⁷⁸ this drug has been found to precipitate rather than to control grand-mal seizures. It also often causes photophobia, skin rashes or diminution of the white cells, particularly the neutrophils, of the blood. Two deaths from aplastic agranulocytic anemia have been reported.⁷⁹⁻⁸⁰ Monthly blood examinations of patients taking this drug should prevent repetition of these disasters.

Demonstration that Tridione seems to have a specific action on the type of seizures associated with an alternate dart and dome formation of the electroencephalogram encourages further laboratory and clinical studies.

CEREBRAL PALSY

Cerebral palsy is admittedly a frequent and serious condition. Recently, a series of articles suggested treatments with drugs, such as prostigmine⁸¹⁻⁸² and curare, and gave publicity to its educational aspects. Public interest has been excited, and medical advice is being sought by parents whose hopes are high. The urgent need at the moment seems to be not so much information on details as a sound basic philosophy.

By convention, the term "cerebral palsy" is used to describe an abnormality in children who have motor disturbance due to cerebral lesions that have been present from birth. This definition should probably be extended to include cases with onset during the early years of childhood. Obviously, a clear distinction is necessary between cases in which extensive medical study of progressive, active disease may be needed and those in which active disease does not appear to be involved. It is only the latter problems that are discussed here.

The causes of cerebral palsy, as defined above, are, of course, many. There is certainly a group that depends on heredity. Cases of this type seem to be rare and are certainly overemphasized in the literature. A second group depends on vaguely understood prenatal disease or accident to the mother.

Recent work on German measles in the early months of pregnancy has called attention to this phase of the subject, and the occurrence of cerebral palsy in children of mothers who have had bleeding

to do well enough on the usual four-hour schedule, with only one or two feedings at breast during each of the first two postnatal days. A few babies, however, seem to be comfortable only on more or irregularly spaced feedings, this is true of both breast-fed and bottle-fed children. In the course of a few weeks on such a schedule, babies tend to cut down on the number and frequency of feedings, so that five feedings a day usually suffice within a few weeks after birth. The physiologic soundness of this method is, of course, attested by the competitive success of mammals in general.

In administering such feedings it should be realized that the reaction of the baby to either overfeeding or underfeeding is much the same, crying being the outstanding symptom. The underfed baby characteristically takes feedings eagerly and hunts for more food when the supply is exhausted, whereas the overfed infant tends to oversleep the next feeding. Hunger in infancy is akin to pain, and pain unrelieved often leads to anxiety and panic. In the majority of cases this mechanism is the foundation of so-called "colic." It is certainly a fact that babies of a few days or weeks cannot be trained to do without a feeding at night or other times. If the desire for food arises, it is in no sense volitional, but is an expression of physiologic need. The sooner this need is met, the faster the baby will be able to gain and store food to allow it to sleep for longer periods, and the less panic and anxiety will have been stimulated.

The introduction of semisolid foods must wait on the development by the infant of the ability to swallow them, and feeding of starches, ability to digest them. An incompletely satisfied appetite helps the baby to want to take new foods, but a really hungry baby expects sucking to be the means to satisfaction and will usually not accept food from a spoon until after at least partially satisfied by breast or bottle, hence, semisolids are usually taken better after the bottle than before.

In the second year appetite is often greatly reduced, many babies in this age group consuming roughly half the food taken a few months previously. At that time a quart of milk a day may well fulfill the caloric needs entirely, and a mixed diet cannot be taken in addition. Drastic cutting of the size of servings — to teaspoonfuls instead of tablespoonfuls and to demitasse instead of eight-ounce cups — will usually keep the child co-operative rather than rebellious at mealtime. Following infections, similar measures may be necessary for a few weeks.

The frequency and character of stools, especially in breast-fed babies, are often far too carefully supervised. Since the stools of the breast-fed infant never become hard and bulky as those of formula-fed babies often do, there is no reason why the infant should have stools at any prescribed interval, certainly, many do well moving their bowels only once

or twice a week. On the other hand, some thriving breast-fed babies have many loose, green stools a day. Except for the housekeeping inconvenience, no harm is done, and weaning on this account is not wise.

In bottle-fed babies infrequent stools tend to become hard and may be the cause of rectal fissures, with attendant discomfort and secondary difficulty in bowel training. Proper attention to the formula or the use of a more laxative sugar will usually improve the situation.

Most of the increments of behavior acquired by infants appear by virtue of anatomic and physiologic processes of maturation. Parents know that children sit, stand, walk and talk during stages of natural development. What is not appreciated by many is that babies also give up sucking for their food as they develop — sometimes toward the end of the first year and sometimes not until well into the second year. When the infant is ready to dispense with this method of eating he readily takes to the offered cup and does not need to be "broken from the bottle." Babies so weaned appear to be less likely to suck their thumbs or fingers than those forcibly put on the cup.

Sphincter control is gained by the same process of development. It is acquired slowly in the second year, in most cases, during waking hours and often not until the third or fourth year during sleep. So-called "training" of the infant for stool during the first few months trains the mother or nurse to anticipate the time of the bowel movement and thereby saves laundry, but is of no value. Many babies so "trained," when old enough to control their stools, seem to withhold them purposely when toileted, they are often more difficult to train than those who are first trained when they can understand the process and co-operate. Most babies cannot acquire bladder control in the daytime until well enough developed to announce their needs, and for a long time after this accidents will happen. This point of view is not aimed at relieving the growing organisms of responsibility indefinitely but is oriented toward postponing it until a stage of development appropriate to its assumption has been reached.

School must likewise be regarded as basically a physiologic process of maturation on which the teacher works. Reading readiness tests and the like, given by schools, are a tacit admission by them of the fact. The child placed in the school system at a level beyond his capacity cannot take his responsibility, which for most children is the main aim of education in the long run. A child who must be kept up by extra help and who cannot afford to miss a class or a day at school is usually placed too far ahead in the school system. The temptation to get too far ahead is a strong one, for the child of five or six is so active that the mother is glad to have the school take him off her hands for part of the day at as early an age as possible.

Eosinophilic granulomatous lesions of bone have recently been described by Lichtenstein and Jaffe⁸⁸ and by Green and Farber⁸⁹ and an attempt has been made to place these lesions in their proper category among bone dyscrasias. The former authors believed that they were describing a new clinical and pathological entity, whereas the latter indicated that the lesion was related to the lipid diseases of bone, variously considered under the names of Hand-Schüller-Christian and Letterer-Siwe diseases. Regardless of the true category, the term "eosinophilic granuloma" is a useful one to bear in mind when cyst-like lesions of bone, many of which were formerly thought to be malignant and were frequently diagnosed as multiple myelomas, are being considered.

The early diagnosis and more rational treatment of slipped femoral epiphysis have recently been emphasized in an effort to prevent the severe crippling that ensues when the condition is neglected.^{90, 91} Probably no lesion of developing bone is more serious in end-result than a bilateral slipped femoral epiphysis, which produces degenerative changes in both hip joints. Any child between the ages of nine and fifteen years, particularly if obese, who complains of pain in the hip, knee or anterior thigh should be carefully evaluated, the possibility of a slipped femoral epiphysis being always borne in mind, and early x-ray films of both hip joints obtained. Early diagnosis is essential if a normal hip joint is to be maintained.

Progress in the orthopedic management of poliomyelitis centers around the introduction of the Kenny method of physiotherapy and its supposed conflict with accepted methods of treatment.⁹²⁻⁹⁴ Since varying physiotherapy technics are usually expressions of temperament and background rather than new discoveries, the introduction of a new variation would have excited little comment, were it not for the crusading fervor of its founder and the deliberate and belligerent attack on the older and less dramatic procedures in vogue. The Kenny method emphasized the value of early mobilization of paralyzed extremities by active exercises, as well as the dangers inherent in rigid and prolonged immobilization. All of this is desirable. The rest of the method might be dismissed as redundant, were it not for the unhealthy press, radio and cinema publicity, which tends to overemphasize the value of this form of physiotherapy in the convalescent management of poliomyelitis.

Acute hematogenous osteomyelitis is essentially a disease of children. Treatment has changed radically with the introduction of penicillin.^{95, 96} Therapy in children under two years of age has been conservative, but in older children, treatment in the past was mainly surgical, with incision and drainage and packing of wounds. Chronicity and prolonged invalidism usually resulted. The present management of acute osteomyelitis is to use penicil-

lin as soon as possible after onset and in large doses. The degree of bone damage is directly proportional to the time elapsing between onset and drug therapy. Of great importance is education of pediatricians to the value of early diagnosis and early medical therapy. Frequent examination of the local lesion, however, is necessary, and the indications for surgery should be well outlined. These include abscess formation and persistent and increasing pain and swelling of the affected part, in spite of adequate dosage of the drug. It is highly desirable to take a blood culture on the child before therapy is instituted, since in this manner the organism can frequently be identified and its sensitivity to penicillin determined. Penicillin therapy should be continued for at least three weeks, or longer if indicated. Surgery should always be minimal and directed toward a specific objective, such as evacuating an abscess or decompressing a bone lesion. Extensive bone stripping and packing are obsolete. Closure of the wound around rubber tubes or cannulas and instillation of penicillin solutions postoperatively lead to early healing and minimal scarring and dysfunction, and in most cases acute osteomyelitis heals without the development of chronic osteomyelitis. This type of management of acute hematogenous osteomyelitis represents a drastic departure from the older methods rather than a modification of technics.

Acute osteomyelitis in children was formerly invariably followed by prolonged suppuration and chronic bone infection. The management of chronic osteomyelitis has altered radically with the introduction of penicillin. At present, it is recognized that necrotic material must be removed surgically. Exploration of draining sinuses and sequestrectomy are still fundamental, but with parenteral drug therapy and direct instillation of penicillin into the wound through tubes, early secondary closure is possible and prolonged suppuration and spread of infection to adjacent bone may be avoided.⁹⁷

New technics have been introduced in the treatment of deformities due to unequal length of the lower extremities. Surgical procedures for lengthening shortened extremities have largely been replaced by selective ablation of the epiphyses in the longer extremity. This procedure, usually termed "epiphyseal arrest," is performed during the period of active growth, and the "timing" of the operation is determined by reference to tables that give average growth expectancy for the epiphyses at various ages. Recent studies on the effects of irradiation on epiphyseal growth may result in quantitative reduction in growth by selective roentgenotherapy of epiphyses at various ages, without recourse to surgery. This procedure is still highly experimental and dangerous, and so far not sufficiently perfected to be used clinically, but offers a promising field for the future.⁹⁸

early in pregnancy supports the theory that various unfavorable events during the early months interfere with normal cerebral development

Birth injuries are frequent, and it is extremely important to make a clear distinction between birth injury and obstetric error. The former means that the infant was damaged during the extremely complicated mechanical and chemical stresses involved in the process of delivery.⁸³ There is increasing evidence that a continuous study by obstetricians and their colleagues is throwing light on prenatal asphyxia, the choice of anesthetics, the durability of premature babies, the causes of hemorrhage of the newborn and so forth, as well as on ways to minimize structural trauma during the delivery of full-term babies. All that should be meant by birth injury, then, is that the infant did not withstand the stresses to which it was exposed.

The occurrence of erythroblastosis, with consequent injury to the nervous system, is under constant and productive investigation, and accurate forecasts and preventive measures are available.

Another group of children pass through the perils of birth and the neonatal period and, after a period of normal development, are the victims of some acute encephalopathy, with consequent motor disturbances. Lead poisoning, thrombosis of the cortical veins, subdural hematoma and the various encephalitic processes that occur with measles, whooping cough and the like are examples. Acute and active diseases must be handled by whatever surgical or medical means are available, and no attempt is made to go into this aspect of the problem.

After all evidences of active disease are over, the physician is faced by a task that can be handled in either of two ways. He can take refuge in the hoary and inadequate formula that the nervous system has only two ways of modifying motor patterns. If the anterior-horn cells are damaged, flaccidity will appear, or if any damage above the level of these cells occurs, spasticity will result. There is no validity in this conception, and it should be rejected. On the other hand, the physician can attempt to make a physiologic and psychologic appraisal, which will reveal not only the disability but also the assets of the child, and can then proceed to work out a plan of management.

If this second plan is accepted, the first thing to do is to proceed in an orderly way to determine what the activity of the child is like. From laboratory evidence it is clear that almost complete decerebration may not be inconsistent with life. From this extreme it is entirely possible to go to the most minor and transient disability.

The motor results of cortical injury are to confuse or abolish planned activity. If the basal ganglia are impaired, associated movements are disturbed, with tremor, athetosis and so forth as salient symptoms. In cases of severe diffuse lesions of the whole forebrain, tonic neck reflexes on rotation of the head

are frequently seen with consequent extension on the side to which the chin is turned and with contralateral flexion of the arm and leg.⁸⁴ Cerebellar lesions, of course, are likely to produce ataxia. It is not difficult to make a rough physiologic appraisal and to compare it with normal behavior at the appropriate age.

Since intelligence is obviously one of the elements in motor control and certainly the controlling factor in effectiveness from the social and economic point of view, an effort should be made to investigate it. Conventional psychometric examination with the result expressed as an intelligence quotient is useful but treacherous. An evaluation by a psychologist who is familiar with handicapped children is better, but even then a single test is less valid than a series at intervals of a year or so.⁸⁵

With the psychologic and physiologic data in hand, it is necessary to consider the effect of the disability in terms of growth and development. At some point it may seem wise to use some of the specialized technics, such as pneumoencephalography and electroencephalography, to obtain a picture of the anatomic and physiologic status of the brain.

Neurosurgical treatment seeks to achieve functional balance by subtraction. If a subtracting technic, such as nerve section, is proposed, it appears reasonable to demand that the family be acquainted with the available physiologic capital from which subtraction is suggested. In the same way, if elaborate and prolonged training procedures are advised, some definite idea of the aim of the procedures should be mapped out.⁸⁶ At the moment it seems clear that many patients are being ingeniously treated as children, without any distinct notion of the ultimate results in terms of adult competitive activities.

The numerous organizations that are dealing with the disabilities of children will be wise if they face resolutely the disconcerting fact that the average child suffering from cerebral palsy comes to adult life unprepared for the competitive world that may be too much for him. The test of successful guidance during childhood comes at adolescence or in early adult life. So far, the results have not been good.

ORTHOPEDIC SURGERY

A new method of treatment of congenital clubfoot was introduced by Denis Browne in 1933, in which the feet were strapped to metal plates connected by a cross bar. Correction was obtained by forceful kicking on the part of the infant. This procedure was reintroduced and modified by Thomson of Toronto in 1942 and has greatly facilitated the early correction of congenital clubfeet.⁸⁷ It has proved a valuable adjunct to the usual methods of correction by manipulation and plaster casts. Emphasis should be placed on the institution of early treatment, since this technic is particularly applicable to the newborn infant, and the earlier treatment is instituted, the better the end-result.

theories are listed in a recent review.¹¹⁷ One report presents questionable evidence and analysis implicating heredity as the basis of the disorder.¹¹⁸ The wide variations of clinical appearances of this disorder are now apparent. These range from the association with meconium ileus in the newborn to the chance finding of patients five to nine years of age in relatively sound states of nutrition and with minimal pulmonary signs.

In the original reports most of the infants died before two years of age. The present therapeutic efforts appear to be increasing the survival period of these patients. Such treatment comprises provision of an adequate diet, substitution therapy in the form of pancreatin and attack on the pulmonary lesions so far as superimposed infection is concerned. In this connection Farber¹¹⁹ has emphasized the presence of a basic lesion in the lungs dependent on the production of abnormal secretions by the mucous glands. Some exception has been taken to this view in a recent report by Wigglesworth,¹¹⁷ but this point is of paramount importance in a consideration of therapy for pulmonary lesions. If altered secretions form the basis of the disease in the lungs, little can be expected from the effort aimed at eradication of superimposed infection. On the other hand, if the infection that is frequently present constitutes a significant portion of the pathologic process in the lungs, it is imperative to focus therapeutic effort toward its eradication, and the results to be expected might be more favorable. The use of sulfonamides orally and of penicillin intramuscularly has met with only partial success in the control of infection. Recently, the use of penicillin and sulfonamides in the form of aerosol inhalation therapy has provided a new approach to the treatment of intrapulmonary infections.^{120, 121} Experience reported recently indicates that the pulmonary lesion can be considerably influenced by this sort of treatment.¹²² A number of patients have shown considerable clearing of the pulmonary infiltration, with corresponding improvement in their clinical well-being, as revealed by a gain in weight and subsidence of cough and fever. It is quite clear, however, that the entire pulmonary lesion is not obliterated, since much of the infiltration remains and some wheezing or cough may persist. Furthermore, the patients are still extremely susceptible to recurrences of pulmonary infection.

Complete descriptions of the roentgenologic features of this disease have appeared.¹²³ In Neuhäuser's¹²⁴ paper particular attention has been devoted to the roentgenologic characteristics of meconium ileus, with the elucidation of certain helpful diagnostic signs.

There is a genuine need for a simpler means of establishing the diagnosis of fibrosis of the pancreas once it is suspected. A new approach to this problem utilizes a rise in amino acid level in the blood following a test meal.¹²⁵ In patients with fibrosis of the

pancreas who have no enzymes in the duodenum, there is little fluctuation of the postprandial amino acid level. Other chronic disturbances of intestinal absorption, such as celiac disease, in which there are normal enzymes in the duodenum, show a significant and comparatively high rise of amino acid level in the blood after the test meal.

Celiac Disease

The reports of the successful treatment of adult sprue with folic acid naturally arouse curiosity concerning similar effects in celiac disease of childhood.¹²⁶ In this clinic we have treated 8 well established cases of this disorder with folic acid without any effects on the steatorrhea or any of the other clinical or laboratory features of the disease.¹²⁷ Two patients with the diagnosis of celiac disease were treated by English physicians with folic acid, and benefit was reported.^{128, 129}

In all methods of equalizing leg length, careful and accurate measurements at various intervals are essential. A useful procedure of accurately measuring the bones of the lower extremities has recently been introduced.⁹⁹ It is essential that physicians in pediatrics and general practice appreciate the possibility of equalizing leg lengths and thus of preventing serious deformities in adult life. Children with lower extremities of unequal length should be referred for orthopedic treatment long enough before the time of natural closure of the epiphyses so that equalization by arrest is possible.

GASTROINTESTINAL DISORDERS

Acute Diarrheal Disease

Progress in the understanding of the causes of diarrheal disease has received considerable impetus from recent work on the isolation of viruses from patients with diarrhea.¹⁰⁰⁻¹⁰³ These studies are particularly stimulating because the search for a causative organism in the form of bacteria has frequently been disappointing. In spite of the tremendous reduction in the incidence of diarrhea there has continued to be frequent epidemic and endemic diarrhea whose cause remains obscure.

The use of the gamma-globulin fraction of human serum had no influence on the course or mortality of infants suffering from epidemic diarrhea of the newborn.¹⁰⁴ It will be of interest to watch the result of further studies along these lines, provided that viruses are found as a frequent cause of diarrhea.

Great progress has been made in the past decade in the treatment of the effects of diarrhea by repair solutions calculated to correct dehydration and acidosis. The importance of establishing renal function as an initial phase in the correction of the disturbed serum electrolyte pattern has been re-emphasized in a recent report.¹⁰⁵ It is opportune that this should be stressed in the light of current developments in elaboration of repair solutions. It should never be forgotten that the most sophisticated repair solution cannot be depended on to replace the wisdom of an alert and capable kidney in restoration of the normal electrolyte pattern.

Up to the present attention has been focused mainly on the major deficits of sodium and chloride resulting from diarrhea. It has long been recognized that other deficits existed, not only in the blood plasma but also in the intracellular electrolyte system.^{106, 107} Particular interest now centers on the deficit of potassium. Further information regarding the loss of potassium from the body during diarrhea is provided by recent contributions.¹⁰⁸ That potassium may be provided in a satisfactory solution and this deficit safely corrected has also been reported.^{109, 110} Details for the preparation and use of this repair solution are given in these reports. In the group of patients receiving this treat-

ment, the mortality was considerably reduced, and some of the symptoms were apparently relieved.

It is difficult to determine the symptoms that can be attributed to a deficit of potassium. Symptoms expected from low levels of serum potassium are those secondary to impaired functioning of striated muscle—for example, diaphragmatic and myocardial paralysis.¹¹¹ Considerable definition of all symptoms is still required. Furthermore, mortality alone may not suffice for the complete evaluation of any beneficial effects of the addition of potassium to a repair solution. This has been illustrated by the recent experience of attempting to evaluate the usefulness of amino acid-containing solutions to replace the nitrogen deficit that occurs in acute diarrhea. The validity of repair solutions to provide materials that correct all deficits occurring in acute diarrhea will be most adequately appraised when the results in patients suffering from all types of diarrhea can be evaluated, in contrast to the results in a single epidemic of diarrhea.

A note of warning is pertinent regarding certain dangers involved in the parenteral administration of solutions containing potassium ion. In patients suffering from dehydration and acidosis, the level of potassium in the serum may already be somewhat elevated.¹¹⁰ If further potassium is supplied by a repair solution either before renal regulatory mechanisms are restored or too rapidly, the level of potassium in the serum may reach a toxic level—an accident that actually occurred in an infant under such therapy.¹¹² This serves to re-emphasize the basic consideration that the restoration of renal function with sodium chloride and glucose solutions should be the initial phase of therapy.

Patients in a severe state of disturbed serum electrolyte pattern associated with either adrenocortical insufficiency or renal failure might well have their fate imperiled by potassium-containing solutions if the condition were not suspected. Such patients are regularly encountered.^{113, 114} In this clinic we have already had a nearly disastrous result from the administration of a potassium-containing repair solution to a child presumably suffering from adrenocortical insufficiency even though urine flow had been first re-established with glucose and sodium chloride solutions.

It now appears that sulfadiazine is as useful as any of the more specialized sulfonamides, such as succinylsulfathiazole and sulfaguanidine, in the treatment of the acute bacterial dysenteries in infants and children.¹¹⁵

Oral streptomycin has been advocated and used with some success in the treatment of infectious diarrhea due to specific sensitive enteric organisms.¹¹⁶

Fibrosis of the Pancreas

Clinical and pathological reports concerning this disease continue to appear with regularity. The cause of the disorder remains obscure. The current

CASE 33241

PRESENTATION OF CASE

A sixty-three-year-old man was admitted to the hospital because of heartburn and abdominal pain.

He complained of heartburn for the previous two years with a dull, constant occasionally sharp pain across the upper abdomen that had extended into the back, especially in the right infrascapular region, in the preceding two months. "Pills" had no effect on the pain, but he felt better when lying on the left side. Three months prior to admission a gastrointestinal series at an outside hospital showed no evidence of ulcer but did show a diaphragmatic hernia. Immediately following the x-ray studies the patient ate a heavy meal, with subsequent repeated vomiting for one day. About that time he noticed slight constipation and subsequently had two black stools. About a month and a half before admission painful ankle edema and occasional shoulder, elbow and wrist pains began. He also noted increasing weakness and a weight loss of 25 pounds in the three months prior to admission.

Physical examination revealed a well developed man showing evidence of recent weight loss. A Grade I apical systolic murmur was noted, with occasional extrasystoles but no enlargement of the heart. The lungs were clear. There was slight tenderness to palpation just beneath the right costal margin, but the liver and spleen were not felt. A few observers felt a deep but indefinite palpable mass in the right upper quadrant. There was a ++ to +++ pitting edema of the lower legs, more so on the right. The temperature was 100°F, the pulse 96, and the respirations 20. The blood pressure was 130 systolic, 80 diastolic.

Examination of the blood showed a hemoglobin of 13 gm and a white-cell count of 16,500, with 71 per cent neutrophils. The urine was normal, as were the stools. The serum protein was 6.2 gm per 100 cc, with an albumin-globulin ratio of 0.9. The nonprotein nitrogen, prothrombin time, amylase and fasting blood sugar were within normal limits. A blood Hinton test was negative. A Graham test did not reveal a gall-bladder shadow.

An intravenous pyelogram was essentially normal. There were old compression deformities of the fourth and fifth lumbar vertebrae and moderate degenerative changes of the spine. An x-ray film of the chest revealed moderate scoliosis of the thoracic spine, with a convexity to the right, and calcification of the wall of the aortic arch. A barium enema disclosed no evidence of intrinsic disease. The gastrointestinal series revealed a small hiatus hernia that reduced itself while the patient was in the upright position. No other abnormality was found.

On the fourth hospital day following an enema the patient began to perspire and fainted. He stated that he had passed a large black stool, but he was on iron therapy and the feces were not saved for examination. During the night of the fourth hospital day he had a severe attack of epigastric pain, which was relieved by firm rubbing of the upper abdomen. The following afternoon, ten minutes after finishing lunch, he developed a boring pain running from front to back in the epigastrium without nausea or vomiting. Sitting up did not relieve the pain. Another Graham test showed no filling of the gall bladder. Duodenal drainage on the seventh hospital day revealed clear, yellow fluid but no sign of blood. Examination of the material disclosed numerous bile-stained white cells and crystals. A cephalin-flocculation test was + + +, both in twenty-four and in forty-eight hours. The serum amylase determination was 29 units, the blood calcium 7.2 mg and the phosphorus 3.7 mg per 100 cc, and the phosphatase was 4.5 units. An electrocardiogram was normal. In a bromsulfalein test the five-minute sample was too dark to read, and in forty-five minutes there was 22 per cent retention of the dye. Subsequent to the duodenal drainage the patient developed a fever, the temperature rising to 101°F. each day, and the pain was rather severer than at the time of entry.

At the end of two weeks the temperature became normal, and on the seventeenth hospital day a laparotomy was performed. At operation no abnormalities could be discovered on palpation or inspection of the abdominal viscera. Because of the positive Graham test on two occasions and the pus and crystals in the duodenal drainage, the gall bladder was removed from above downward without incident. The common duct, which was then opened and explored, contained clear bile, and probes passed readily into the duodenum. A liver biopsy was also performed.

On the fourth postoperative day the patient complained of upper abdominal pain similar to that before operation. The next day he complained of numbness and paresthesias in the hands, and neurologic examination revealed diminished sensation to pinprick in the distal phalanges of the left hand and over the lateral aspect of the right lower leg and foot. On the following morning the patient awoke complaining bitterly of pain and inability to

perhaps spoil the fun of these exercises — that is, fun for you but not for me. I thought that, instead of going round and round this diagnostic circle, I should take one symptom and see what I could do with it.

The peculiar complication of this case is the peripheral neuritis. I do not believe that it was due to nutritional deficiency, I say so because of the onset. The pain, which was sudden in its development, was patchy and not symmetrical, and hardly compatible with a diagnosis of nutritional deficiency.

Was the prothrombin time normal?

DR JONES: Yes.

DR RICHARDSON: What about infectious polyneuritis? I have never seen a patient with this disease who reacted in this fashion. Many of the

metastases and no evidence of tumor on abdominal exploration.

A final possibility is some other type of central-nervous-system infection or neoplastic invasion. There is no report of a lumbar puncture. Nothing in the blood picture supports a diagnosis of sepsis, although the patient was running a mild fever.

Could this neuritis have been arterial in origin? I do not understand why, when an artery becomes plugged, neuritic symptoms appear. I do not want to go more deeply into this question.

Periarteritis nodosa is a diffuse disease associated with neuritis, fever and abdominal pain, and that diagnosis must be considered in this case. Again, the onset of the neuritis was peculiar for periarteritis nodosa. The type of abdominal pain due

FIGURE 1

facial nerves are first involved, and sometimes these are the only nerves affected. There are other types of infectious polyneuritis, but I do not believe that there is much evidence for obscure diseases.

Did this man have active tabes, with everyone thrown off the track? The pain of tabes is not of this type. Usually, it involves the lower limbs, with, in the early stages, no definite evidence of impaired sensation.

What about metastases to bone or malignant tumor in the region of the sacral or brachial plexuses? This has not been ruled out and remains a possibility, although there was no x-ray evidence of bone

to small mesenteric thrombosis or infarctions is usually referred to the midline and is more generalized. Although one should bear in mind the possibility of periarteritis nodosa, I do not believe that in this case one can make such a clear-cut diagnosis. I come down to the fantastic theory that this man had arterial disease, which was perhaps localized in the region of the abdominal aorta, at the level of the pancreas. All this midepigastrie boring pain going through to the back is quite typical of pancreatic pain, or pain in that area. I suspect that the patient had an ulcerating lesion in the region of the pancreas, with erosion into the aorta and actual

move the left foot. Physical examination showed no change in color or temperature of the foot. There was anesthesia over the entire leg below the knee except for a 5-cm. band along the medial aspect.

DIFFERENTIAL DIAGNOSIS

DR. WYMAN RICHARDSON: I might begin by saying that I have arrived at a fantastic conclusion, and that I apologize ahead of time for it.

"A few observers felt a deep but indefinite palpable mass in the right upper quadrant." I think that one must forget about this mass, with only a few observers feeling a deep but indefinite mass; it remains deeply obscure and quite indefinite to me.

This is a case in which a blood smear would have been helpful in the differential diagnosis. I shall point out here that a leukocytosis of this extent, with only 70 per cent neutrophils, is strong evidence against pyogenic infection as the cause of the symptoms, and also against bacterial endocarditis alone as the cause of the symptoms. The blood picture suggests fairly recent and acute blood loss or infarction, or if there were evidence of red-cell regeneration it would suggest the possibility of bone-marrow encroachment. We do not know whether there was red-cell regeneration or not. There are other kinds of infection that might cause this type of blood picture, but without further data, I do not believe that one need consider them. This picture is compatible with loss of blood into a cavity or with extravasated blood.

I assume that a good many stool examinations for occult blood were done and were negative.

I wonder why the albumin and globulin were not reported in grams, rather than the albumin-globulin ratio. It is easier for me if the report is in grams, my mathematics not being too good. In this case I should say that there was about as much albumin as globulin.

Perhaps we should see the x-ray films. I am anxious to know if there is any evidence suggesting tumor involving bone in either the lumbar or the cervical spine. I do not believe that films of the cervical spine were taken, however.

DR. TOUFIC KALIL: The only thing that I can see is the hiatus hernia that was described as being readily reducible on standing.

DR. RICHARDSON: I am uncertain whether the hiatus hernia accounted for this man's pain. Do you see the deep and indefinite mass in the right upper quadrant? Nothing was observed in that area at operation.

DR. KALIL: No.

DR. RICHARDSON: Is this an old fracture of the spine?

DR. KALIL: All the bones are decalcified. Without a lateral view of the lumbar spine, one cannot tell much about it. There is no localized destruction. The intravenous pyelogram is normal.

DR. RICHARDSON: The question is, Did this man faint because he had a sudden hemorrhage? I should say that a man who fainted suddenly from hemorrhage would not immediately pass a black stool. To account for the fainting, he would have to have had a massive hemorrhage, and if he immediately passed a stool it would definitely have been bloody. What else could happen to a man who had an enema? I suppose that many things could occur. Patients may feel faint without any pathologic reason. I think that this episode may have been significant, although I am not quite sure of what. One could have perforation of the bowel following an enema, but there was no evidence of peritonitis following it. For the moment I shall say that perhaps something occurred when the enema was given. It may turn out to be of some importance, but it was probably not a sudden acute hemorrhage. No guaiac-positive stools were reported following this incident.

The record does not state whether the crystals found in the duodenal drainage were cholesterol or bilirubin. I do not rely too much on the cephalin-flocculation test. I wonder if it was associated with the slight increase in globulin. The serum amylase was 29 units per 100 cc. I believe that is normal. Do you agree, Dr. Jones?

DR. CHESTER M. JONES: Yes.

DR. RICHARDSON: The blood calcium was somewhat low, as was the serum albumin. I do not know whether that is significant or not. The bones were somewhat decalcified. Most of the blood chemical findings were normal. The phosphorus was slightly high but, I should think, within normal limits.

It is not stated whether the bromsulfalein test was done with a 2-mg. or a 5-mg. dose, presumably, it was 5 mg. I should say that there was slight increase in bromsulfalein retention but within a range that was not sufficiently characteristic to lead to any specific diagnosis. At least, I shall say that it was not severe enough to make it certain that there was any considerable degree of hepatic failure.

Evidently, it was considered quite possible that this man had gallstones. I cannot imagine that the surgeon did not open the gall bladder, and I gather that no stones were found, although nothing is said. I believe that the gall bladder was removed more or less on theoretical grounds.

The record does not mention peripheral arterial pulsation, which I think is extremely important in this case.

One of the things that helps a great deal in these discussions is the knowledge that the patient died. I do not know whether this patient died or whether he got well. I might say that I am doubtful if Dr. Castleman can make a diagnosis on the basis of a small liver biopsy, and I suspect that he had more material to examine than a small piece of liver. I assume that the patient's subsequent course was so characteristic as to give the diagnosis away and

DR RICHARDSON Regarding the nonfilling gall bladder, I meant to suggest that it might have been due to a poorly functioning liver. It will be recalled that there was some degree of dye retention.

CLINICAL DIAGNOSIS

Carcinoma of body of pancreas?

DR RICHARDSON'S DIAGNOSIS

Ulcerating lesion, pancreatic region, causing aortic erosion and dissection

ANATOMICAL DIAGNOSES

Periarteritis nodosa involving gall bladder and liver
Infarcts of gall bladder

PATHOLOGICAL DISCUSSION

DR CASTLEMAN The gall bladder that we received looked fairly normal except for a few small, dark, hemorrhagic, questionably ulcerated areas on the mucosa. The rest of the mucosa was smooth, shining and velvety. On microscopical examination we found in the wall of the gall bladder many arteries whose walls were necrotic and heavily infiltrated with polymorphonuclear leukocytes and lymphocytes. The findings were quite characteristic of periarteritis nodosa. Elastic-tissue preparations showed marked destruction of the elastica. Some of the vessels were thrombosed and accounted for the focal mucosal ulcerations, which were really focal infarctions (Fig 1). We found the same process on liver biopsy — extensive necrosis of the small arteries, with thrombosis. In places organization of the thrombi with recanalization had occurred (Fig 2).

This man is still on the ward, Dr Richardson, and we do not know what the final situation is. Can you tell us how he is, Dr Dahl?

DR LEWIS K DAHL He is going downhill rapidly.

DR RICHARDSON Did he ever have any eosinophilia?

DR DAHL No.

DR RICHARDSON Had he ever been given any sulfonamides?

DR DAHL We could not obtain any history of sulfonamide administration. The patient does not speak English very well, but he gave no history of taking tablets that suggested the sulfonamides.

DR RICHARDSON What was the anatomic cause of the boring epigastric pain?

DR CASTLEMAN I believe that the infarction of the gall bladder could have caused the pain.

CASE 33242

PRESENTATION OF CASE

A seven-month-old male infant was admitted to the hospital because of a mass in the right abdomen. The child was born after an uneventful pregnancy and weighed 8 pounds, 12 ounces. Development

was normal, and the day before admission his mother first noticed a mass in his right abdomen.

Physical examination showed an overnourished infant in no distress. There was a firm, rounded, fairly smooth, nontender mass occupying the right half of the abdominal cavity and extending from beneath the right costal margin to just below the level of the right iliac crest. The rest of the examination was negative.

Examination of the blood revealed a white-cell count of 19,600, with 49 per cent neutrophils, 45 per cent small lymphocytes, 4 per cent monocytes and 2 per cent eosinophils. Urine and stool examinations were negative. An intravenous pyelogram revealed an unusually large right kidney, which was smooth. The left was obscured by gas but appeared within normal limits. The right kidney produced bulging of the abdominal wall laterally. Excretion of dye was prompt in both kidneys. The urinary passages on the left were poorly seen but showed no gross abnormality. On the right there was gross crowding of the calyces in the upper half of the kidney upward and of the lowermost calyx downward and inward. There was no evidence of gross invasion of the calyces or pelvis.

On the fifth hospital day an exploratory laparotomy was performed.

DIFFERENTIAL DIAGNOSIS

DR LEO BURGIA This brief history leads one at once to the problem of the etiology and nature of an abdominal mass in a seven-month-old infant who had previously been well.

The x-ray report of an enlarged kidney producing bulging of the abdominal wall suggests that the mass was at least retroperitoneal. This simplifies matters somewhat in that a host of abdominal possibilities, such as congenital cysts, reduplications, hepatoma, abdominal lymphoma and Hodgkin's disease, may be excluded.

Since we have decided that the tumor mass was retroperitoneal, our next consideration is whether or not it was malignant and finally, what was its nature. From a practical standpoint one should follow Farber's* generalization, "Every solid mass in an infant or child should be regarded as a malignant tumor and removed in its entirety for histological examination and determination of its exact nature." Presumably, this was carried out in the present case.

For purposes of discussion we should rule out a "benign" condition such as cystic disease of the kidney — multiple or single. There is no evidence of abnormal kidney function such as albuminuria or hematuria. Of course, with small cysts there may be sufficient normal renal tissue for an infant of this age. With a mass such as that described, how-

*Farber, S. Malignant tumors in early life. In *Textbook of Pediatrics*, Fourth edition, 1320 pp. Philadelphia: W. B. Saunders Company, 1945. Pp. 315-323.

dissection of the aorta up and down. He may have had a moderate degree of cirrhosis of the liver, but I do not believe that it was significant. If this is not a fantastic diagnosis, I have never heard of one.

DR. WALTER BAUER: I believe that you should not have lost the diagnosis of periarteritis nodosa.

DR. RICHARDSON: I was going to flip a coin but then decided on a flat-footed diagnosis.

DR. BAUER: The white-cell count was 16,000, which is suggestive, and the other symptoms are readily explained on the basis of periarteritis nodosa. It certainly accounts for the recurring at-

DR. BENJAMIN CASTLEMAN: Will you tell us about the operation, Dr. Taylor?

DR. GRANTLEY W. TAYLOR: I should apologize for operating at all. The patient had lost a good deal of weight, had become progressively weak and had a somewhat elevated white-cell count and intermittent fever. The most incapacitating symptom was the severe pain that went through to the back. The only evidence that we could tie up with that as possibly being helpful was the character of the duodenal drainage and the two positive Graham tests. There was no jaundice, and we thought that

FIGURE 2

tacks of abdominal pain. I should make a diagnosis of periarteritis nodosa.

DR. RICHARDSON: I accept that as a possible diagnosis. I doubt if the patient had it. Does anyone else want to suggest an alternative diagnosis?

A PHYSICIAN: How about acute porphyria? Would it fit in with the findings in this case?

DR. RICHARDSON: I had not thought of porphyria as a disease. I considered lead colic and neuritis, which I did not think probable. I am not able to rule out acute porphyria.

DR. JONES: We had a case of porphyria six weeks ago with repeated attacks of severe abdominal pain, and I think that that condition should be included at least in the differential diagnosis.

all these symptoms might have occurred on the basis of carcinoma involving the body of the pancreas or that the patient had disease related to the gall bladder and common duct. I must say that it was a completely negative exploration. The hiatus hernia did not seem to account in any way for the symptomatology. Then the problem was what to do—whether to let him alone, sew him up or take out the gall bladder on the ground that the symptoms were due to gall-bladder disease that was not obvious from external examination of the organs. We also explored the common duct on the suspicion that cholangitis was present, but the bile duct proved to be perfectly normal. We removed the gall bladder and took a liver biopsy, thinking that we might turn up with something.

distorted pelvis but good function, and a normal urine in an otherwise normal infant suggests the presence of a mixed tumor of the right kidney. I believe that this infant had a Wilms's tumor.

DR STANLEY WYMAN: These films show the enlarged right kidney pressing on the lateral wall of the abdomen. The upper and lower calyces in this film are crowded upward and downward respectively, but no definite intrinsic involvement of the walls or the pelvis can be determined. No evidence of disease can be seen in the bones of the spine or chest.

CLINICAL DIAGNOSIS

Wilms's tumor of kidney

DR BURGIN'S DIAGNOSIS

Wilms's tumor of kidney

ANATOMICAL DIAGNOSIS

Wilms's tumor of kidney

PATHOLOGICAL DISCUSSION

DR BENJAMIN CASTLEMAN: At operation Dr Robert R. Linton found a large tumor of the kidney, which he removed without difficulty. It was not adherent to any of the surrounding structures and had not broken through the capsule of the kidney. The tumor measured about 8 cm in diameter and had replaced most of the renal parenchyma, leaving only a narrow rim of cortex (Fig. 1). It appeared to be completely surrounded by a fibrous capsule and did not invade the pelvis or calyces. Microscopically, the tumor was composed of both tubular and spindle-cell elements, which are the characteristic findings in a Wilms's tumor or what is often called "embryonal adenocarcinoma." A few regional lymph nodes removed with the kidney showed only hyperplasia.

ever, one would expect some abnormal urinary findings if it had been due to cystic disease. One would also expect more distortion of the renal pelvis, possibly with an x-ray appearance consistent with the so-called "spider pelvis" deformity. The latter picture is by no means diagnostic of this condition, which has been reported in cases of embryoma of the kidney. Cystic disease is generally bilateral—in 98 per cent of cases, according to some authors

retroperitoneal space and about the adrenal glands. There is no characteristic picture other than the presence of an abdominal mass. One may encounter nonspecific complaints of fever, anorexia, bowel disturbances and so forth. If there has been metastasis to bone, and this is common with neuroblastoma, there may be pain in the extremities.

Embryoma of the kidney is an encapsulated tumor arising within the kidney. The tumor is firm,

FIGURE 1

The prompt excretion of dye by both kidneys is further evidence against such a diagnosis.

With much of the previous evidence one can rule out hydronephrosis due to obstructive uropathy resulting from congenital malformations. Inflammatory processes may likewise be excluded. We might, in passing, mention such benign tumors as lipoma, fibroma and myoma only to note that these are extremely rare and not likely to produce the picture described here.

We are then led to consider at once some of the malignant tumors of this region. In children under two or three years of age the commonest tumors occurring in the renal region are the embryoma of the kidney (Wilms's tumor, or mixed tumor of the kidney) and tumors of the neuroblastoma series. One might also include occasional mixed tumors arising from tissues outside the kidney but in the retroperitoneal spaces. One should perhaps include hypernephroma. There seems to be some question whether such a tumor ever occurs in infancy. I do not believe that we need consider it in this case.

The neuroblastoma may arise within the adrenal medulla or from sympathetic nerve tissue in the

smooth and rounded in outline. It often extends to the midline and to the iliac crest. Since such tumors arise within the kidney, we expect to find distortion of the renal pelvis by x-ray examination. Occasionally, the deformity may be confused with that produced by cystic disease, as I have indicated above. The tumor is usually unilateral. Neuroblastoma occasionally arises within the kidney from inclusions of adrenal medullary tissue present there and consequently gives a picture indistinguishable grossly from embryoma.

The sudden appearance of the tumor one day before admission may be difficult to reconcile with the physical examination on admission. The life history of these tumors, however, includes such phenomena, generally, massive hemorrhage into a tumor that is starting to grow rapidly may make the tumor noticeable in cases in which examination a few days previously has revealed no mass. The elevated white-cell count may have been in response to the hemorrhage or necrosis, or both, that may have been taking place.

The sudden appearance of a firm, smooth tumor mass involving the kidney, with x-ray evidence of a

THE EFFECT OF DI-ISOPROPYL FLUOROPHOSPHATE ON PATIENTS WITH MYASTHENIA GRAVIS

MUSCULAR fatigue characteristic of the weakness in patients with myasthenia gravis is thought to result from an insufficiency of acetylcholine at the myoneural junction. This insufficiency may be due to a decreased formation of acetylcholine (faulty metabolism), to an increased cholinesterase activity destroying the acetylcholine more rapidly than under normal conditions or to a decreased activity of acetylcholine itself, possibly caused by the presence of an antagonistic curare-like substance. There is no unequivocal evidence at present to support a view that any one of these postulates accounts for the chief symptom of myasthenia gravis, but it is agreed by all investigators that the acetylcholine-cholinesterase balance is disturbed at the myoneural junction in this disease. It has been shown, moreover, that cholinesterase is inhibited by neostigmine or physostigmine, the two drugs ordinarily used in the treatment of this disease. Because of the ease with which it is tolerated by patients, neostigmine has replaced physostigmine.

Although neostigmine is reasonably efficient other cholinesterase agents are now under investigation. Recently, di-isopropyl fluorophosphate (DFP), a compound unrelated chemically to neostigmine, was found to produce inhibition of serum, red-cell, muscle and brain cholinesterase in animals. The results of treating myasthenic patients with this drug have now been reported by Comroe and his associates,¹ working at the University of Pennsylvania Medical School and the Medical Research Laboratory, Chemical Warfare Service, Edgewood Arsenal. Bodansky,² while working with the Chemical Warfare Service, first noted the inhibiting power of di-isopropyl fluorophosphate on cholinesterase. When given intramuscularly, it is capable of lowering plasma and red-cell cholinesterase activity to a marked extent and for a prolonged period. The drug is also capable of improving muscle strength in patients with myasthenia gravis. It is not, however, a satisfactory drug to use from the clinical point of view. In the 7 patients treated by Comroe et al., 2 showed little or no benefit, 2 were consider-

ably improved, 1 had marked beneficial effects, and in 2 the results were obscured by peculiarities in the natural cycle of the disease. In no case did the objective or subjective improvement following the administration of di-isopropyl fluorophosphate equal or exceed that produced by the use of neostigmine. Attempts, moreover, to give large doses of the drug resulted in nausea and vomiting and other symptoms referable to the central nervous system. Despite the fact that it lowered the plasma cholinesterase to zero, it produced less clinical improvement than neostigmine in patients with myasthenia gravis.

The reason for the relative failure of di-isopropyl fluorophosphate as a therapeutic agent has not been fully determined. Being a highly lipid-soluble agent whereas neostigmine is a highly water-soluble agent, it may not find its way into the myoneural junction as readily as does neostigmine. If the drug is given to man in doses large enough to produce improvement throughout the body, it cannot be administered regularly because of its untoward effects on the gastrointestinal tract and the nervous system. The better results obtained by neostigmine however may be due to the possibility that neostigmine has a direct action on skeletal muscles that is not shared by di-isopropyl fluorophosphate. Whatever final conclusions are reached regarding the reason for its relative failure, the drug may prove to be of some use when utilized, in nontoxic doses, to obtain its prolonged effect. At the same time neostigmine can be given to obtain the characteristically stronger action. Since neostigmine, however, tends to protect cholinesterase from inactivation by di-isopropyl fluorophosphate, it seems unlikely that the latter will ever be as valuable as neostigmine in the treatment of myasthenia gravis.

BLUE SHIELD ADVANCES

ON JUNE 1, 1947, Blue Shield took an important step forward. On that date its present program of surgical and obstetric benefits in the hospital was extended to include medical (nonsurgical) benefits in the hospital and surgical and obstetric benefits outside the hospital. At the same time, a new schedule of fees for services rendered to holders of Blue Shield policies became effective.

Undoubtedly the latter will receive the utmost attention and a certain amount of criticism, particularly from those participating physicians who

are surgeons. The schedule is the result of careful study and of many time-consuming meetings of the committees appointed to prepare it. The committees were composed of specialists in their various fields, who agreed that Blue Shield fees should not be based on the customary value of a specialist's services but on the ability of individuals and families in the under-income group to pay for such services. Much consideration was given to the relative difficulty of procedures not only within the specialties but also between the specialties, with the result that procedures of comparable difficulty in, for example, ophthalmology and urology were assigned similar fees so far as it was possible to do so. At first glance the level of fees may seem low, but when it is remembered that they apply to low-income patients, many of whom were previously medically indigent and to patients who were formerly poor credit risks, their adequacy is more easily visualized. It should also be recognized that the schedule applies on a state-wide basis.

With nearly 600,000 persons covered, Blue Shield is now the second largest and one of the most prosperous medical-care plans in the Nation, and much of its success is attributable to the fact that physician participation, originally in the neighborhood of 50 per cent, has rapidly climbed to its present level of over 90 per cent. The Blue Shield Board of Directors, made up of one third physicians and two thirds lay persons, is elected by the Executive Committee of the Council of the Massachusetts Medical Society, and before any rules or regulations affecting medical matters can be implemented they must be approved by the Executive Committee. Furthermore, in each district medical society there is a Blue Shield Professional Service Committee, through which the practicing physician can make his voice heard.

The ultimate success of Blue Shield rests primarily on the degree to which the medical profession, collectively and individually, participates. Because of the overwhelming importance of this venture, every physician who is interested in maintaining the voluntary approach to the problem of the costs of medical care and who is not yet a participant should request that he be supplied with an application form. Such letters should be addressed to Massachusetts Medical Service, 38 Chauncy Street, Boston 11.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

NEW APPOINTMENTS

Victoria M. Cass, M.D., has been appointed epidemiologist in the Division of Administration, Massachusetts Department of Public Health. Dr. Cass held the position of teaching fellow in pathology at Tufts College Medical School from 1942 to 1944. Prior to her recent appointment, she was house officer, Medical Service, Boston City Hospital.

Joseph H. Hanson, M.D., formerly of the Medical Corps, A.U.S., has been appointed epidemiologist in the Division of Communicable Diseases, Massachusetts Department of Public Health.

Margaret M. Haehnel, M.S., has been appointed public-health social-work supervisor in the South Metropolitan District of the Massachusetts Department of Public Health. Mrs. Haehnel has been associated with the Worcester Children's Friend Society, the Family Welfare Society, of Springfield, and the Pondville Cancer Hospital.

Claire F. Ryder, M.D., formerly research resident and teaching fellow in tropical medicine at the Boston City Hospital, has been appointed epidemiologist in the Division of Administration, Massachusetts Department of Public Health. Prior to attending the Army Medical School in Washington, D.C., Dr. Ryder was house officer at the Boston City Hospital.

A. Geraldine White, A.B., has been appointed research consultant in the Child Growth and Development Program, Division of Maternal and Child Health, Massachusetts Department of Public Health. Miss White formerly held the position of health education assistant with the Middlesex Health Association.

Isah L. Salzman, M.S., who held the position of social worker with the Boston Department of Public Welfare, has been transferred to the Northeastern District of the Massachusetts Department of Public Health.

Brooks Ryder, M.D., a former captain in the Medical Corps, A.U.S., has been appointed epidemiologist in the Division of Local Health Administration, Massachusetts Department of Public Health. Prior to his appointment, Dr. Ryder was research assistant in anatomy at Tufts College Medical School. He served his internship at the Boston City Hospital.

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Conduction Anesthesia. Clinical studies of George P. Pitkin, M.D. Edited by James L. Southworth, M.D., and Robert A. Hingson, M.D. 4°, cloth, 981 pp., with 606 illustrations. Philadelphia: J. B. Lippincott Company, 1946. \$18.00.

Modern Management in Clinical Medicine. By F. Kenne Albrecht, M.D., senior assistant surgeon, United States Public Health Service, and Kansas State Tuberculosis Consultant. 4°, cloth, 1238 pp., with 237 illustrations. Baltimore: Williams and Wilkins Company, 1946. \$10.00.

Intracranial Complications of Ear, Nose and Throat Infection. By Hans Brunner, M.D., associate professor of otology, University of Illinois College of Medicine. 8°, cloth, 444 pp., with 95 illustrations. Chicago: Year Book Publishers, Incorporated, 1946. \$6.75.

Anesthesia in General Practice. By Stuart C. Cullen, M.D., head of Division of Anesthesiology, Department of Surgery, State University of Iowa Hospitals, and associate professor of surgery (anesthesiology), State University of Iowa College of Medicine. 8°, cloth, 260 pp., with 36 illustrations and 4 tables. Chicago: Year Book Publishers, Incorporated, 1946. \$3.50.

Treatment of Bronchial Asthma. By Vincent J. Derbes, M.D., instructor in medicine and in preventive medicine, Tulane University of Louisiana School of Medicine, assistant visiting physician, Charity Hospital of Louisiana, and director of the Department of Allergy, Ochsner Clinic, and Hugo T. Engelhardt, M.D., instructor in clinical medicine, Baylor University College of Medicine, Houston, Texas, adjunct in medicine, Jefferson Davis Hospital, Houston, and visiting physician, Charity Hospital, New Orleans. With chapters by a panel of contributors. 8°, cloth, 466 pp., with 61 illustrations. Philadelphia: J. B. Lippincott Company, 1946. \$8.00.

Peptic Ulcer: Its diagnosis and treatment. By I. W. Held, M.D., attending physician, Beth Israel Hospital, and A. Allen Goldbloom, M.D., assistant clinical professor of medicine, New York Medical College and Flower and Fifth Avenue Hospitals, associate physician, Beth Israel and Metropolitan Hospitals, and associate cardiologist, Beth Israel Hospital, New York City. 8°, cloth, 383 pp., with 110 illustrations. Springfield, Illinois: Charles C. Thomas, 1946. \$6.50.

Shock Treatment and Other Somatic Procedures in Psychiatry. By Lothar B. Kalnowsky, M.D., research associate in psychiatry, Columbia University, College of Physicians and Surgeons, and New York State Psychiatric Institute and Hospital, and assistant neurologist, Neurological Institute of New York, and Paul H. Hoch, M.D., assistant clinical psychiatrist, New York State Psychiatric Institute and Hospital, and instructor in psychiatry, Columbia University College of Physicians and Surgeons. With a foreword by Nolan D. C. Lewis, M.D., professor of psychiatry, Columbia University College of Physicians and Surgeons, and director, New York State Psychiatric Institute and Hospital. 8°, cloth, 294 pp. New York: Grune and Stratton, 1946. \$4.50.

Clinical Methods of Neuro-ophthalmologic Examination. By Alfred Kestenbaum, M.D., assistant clinical professor of ophthalmology, New York University, lecturer in ophthalmology, Mt. Sinai Hospital, associate ophthalmologist, City Hospital, consultant ophthalmologist, Psychiatric Department, Bellevue Hospital, and Neurologic Department, Goldwater Memorial Hospital. 8°, cloth, 384 pp. New York: Grune and Stratton, 1946. \$6.75.

Early Ambulation and Related Procedures in Surgical Management. By Daniel J. Leithauser, M.D., chief of surgery, St. Joseph Mercy Hospital, Detroit. 8°, cloth, 232 pp., with 36 illustrations and 6 tables. Springfield, Illinois: Charles C. Thomas, 1946. \$4.50.

Practical Malariology. Prepared under the auspices of the Division of Medical Sciences, National Research Council, by Paul F. Russell, M.D., M.P.H., Parasitology Division, Army Medical School, Luther S. West, Ph.D., head of Biology Department, Northern Michigan College of Education, and Reginald D. Maxwell, Sc.D., professor of zoology, Syracuse University. 8°, cloth, 683 pp., with 238 illustrations. Philadelphia: W. B. Saunders Company, 1946. \$8.00.

ANNUAL ORATION

MEDICAL CARE IN OUR FREE SOCIETY*

LELAND S. MCKITTRICK, M.D.†

BOSTON

The objective of adequate medical care in our free society is to make available to everyone — regardless of race, color, creed, financial status or place of residence — every known essential preventive, diagnostic and curative medical service of high quality. The attainment of such medical care must necessarily be an evolutionary process which will require the co-operation of all concerned over a period of years.

I have chosen as the subject of my oration this paragraph from the *Basic Principles Which Should Govern Medical-Care Plans*, which the Massachusetts Medical Society presented last year. Concise and complete, it stands as a challenge, if not a commitment, to us as members

Available to Everyone Regardless of Financial Status

Financial status as applied to medical care is a relative term. To the head of a household, modest but sound, the cost of an appendectomy for one of the children may be met without undue hardship. Should the head of this household suffer a long and tedious illness, the unavoidable financial obligations assumed may represent a burden that not only is a hardship but also may be overwhelming.

A consideration of the availability of medical care to the people of this Commonwealth must include a study of the income of the prospective recipients as well as of the cost of the services rendered. Interested in and busy with the calls of our patients, few of us have given thought to the earnings of the people of the Commonwealth that we as a profession serve.

It has been with much greater difficulty than would have been anticipated that information was obtained that might give us some reasonably accurate data on the relative number of workers in this state who fell into the different income classes.

Figure 1 is based on data compiled by the United States Treasury Department ‡

Whereas wages in 1942 were at a lower level than those of the present, the wage earners' income was probably higher because of overtime and other incentives used to increase production. To me, this is an impressive picture. It must be kept constantly in mind as we discuss the problem of a program that will make good medical care available to all the people of the Commonwealth.

Good medical care is and will remain expensive, but the continued rising costs of this care are a concern to us all. Yet there must be a ceiling to such costs, or else they cannot continue to be met by too large a segment of our population, and the price put on good health will be out of proportion to that on other necessities and privileges of our daily life.

As one might expect, most of the increasing costs are in hospital and nursing care. Thus, in 1940 the average total per-diem hospital charge, exclusive of professional and special nursing care, to 100 patients in the lowest price accommodation at the Baker Memorial Hospital was \$7.31, and in 1947 this same care cost the patient \$13.40 daily, or \$93.80 per week.

What are the factors responsible for this, and how are they being met? The financial problems of the voluntary hospitals were presented in a forceful and realistic way by Dr. Faxon* in his address at the Ether-Day Exercises last October. Two months later, the Hospital Council of Boston, after careful deliberation, recommended that the hospitals of the Greater Boston area adopt a pay-as-you-go philosophy for meeting rising costs and diminishing voluntary contributions. Specifically, the Council recommended that in the near future hospital rates be

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 20, 1947.

†Associate in surgery, Harvard Medical School; surgeon-in-chief, Palmer Memorial Hospital; surgeon, New England Deaconess Hospital; visiting surgeon, Massachusetts General Hospital.

‡The basis of the data is Table 8, which presents individual returns with net income for 1942 by taxable and nontaxable returns and by net income classes, and also aggregates by states for individual returns with no net income and for taxable fiduciary returns with net income.

The Ego and the Mechanisms of Defense By Anna Freud Translated from the German by Cecil Baines 12°, cloth, 196 pp., New York International Universities Press, Incorporated, 1946 \$4 00

Chronic Diseases and Psychological Invalidism A psychosomatic study By Jurgen Ruesch, M.D. With a foreword by Karl M. Bowman, M.D. From the Division of Psychiatry, University of California Medical School, and Langley Porter Clinic, San Francisco 8°, paper, 191 pp. New York American Society for Research in Psychosomatic Problems, 1946 \$3 00

Urgent Surgery Edited by Julius L. Spivack, M.D., associate professor of surgery, University of Illinois College of Medicine, senior attending surgeon, Columbus Memorial Hospital, Chicago, and attending surgeon, Oak Forest Infirmary Volume I 8°, cloth, 714 pp., with 244 illustrations Springfield, Illinois Charles C Thomas, 1946 \$10 00

Penicillin in Neurology By A. Earl Walker, M.D., associate professor of neurologic surgery, University of Chicago School of Medicine, and Herbert C. Johnson, M.D. resident neurologic surgeon, University of Chicago School of Medicine 8°, cloth, 202 pp., with 72 illustrations Springfield, Illinois Charles C Thomas, 1946 \$5 00

Psychiatric Interviews with Children Edited by Helen Leland Witmer 8°, cloth, 443 pp. New York The Commonwealth Fund, 1946 \$4 50

Personality of the Preschool Child The child's search for his self By Werner Wolff, professor of psychology, Bard College 8°, cloth, 341 pp., with 118 figures New York Grune and Stratton, 1946 \$5 00

Surgical Treatment of the Soft Tissues Edited by Frederic W. Bancroft, M.D., associate clinical professor of surgery, Columbia University, attending surgeon, New York City and Beth David hospitals, consulting surgeon, Veterans Administration, Lincoln and Harlem hospitals, New York City, and Kings Park State Hospital, Kings Park, New York, and George H. Humphreys, II, M.D., Sc.D., Valentine Mott Professor of Surgery, Columbia University College of Physicians and Surgeons, and director of Surgical Service, Presbyterian Hospital, New York City 4°, cloth, 520 pp., with 244 illustrations Philadelphia J. B. Lippincott Company, 1946 \$15 00

Adjustment to Physical Handicaps and Illness A survey of the social psychology of physique and disability By Roger G. Barker, Beatrice A. Wright and Mollie R. Gonick 8°, paper, 372 pp. New York Social Science Research Council, 1946 \$2 00

Radical Surgery in Advanced Abdominal Cancer By Alexander Brunschwig, M.D., professor of surgery, University of Chicago 8°, cloth, 324 pp., with 117 illustrations and 16 tables Chicago University of Chicago Press, 1947 \$7 50

Textbook for Psychiatric Attendants By Laura W. Fitzsimmons, R.N., B.S., M.A., assistant director of nurses and chief neuropsychiatric nurse, United States Veterans Administration, and chairman, Committee on Psychiatric Nursing, National League of Psychiatric Nursing 8°, cloth, 332 pp. New York Macmillan Company, 1946 \$3 50

Diagnosis and Treatment of Menstrual Disorders and Sterility By Charles Mazer, M.D., assistant professor of gynecology and obstetrics, Graduate School of Medicine, University of Pennsylvania, and gynecologist, Mount Sinai Hospital, Philadelphia, and S. Leon Israel, M.D., instructor in gynecology and obstetrics, University of Pennsylvania School of Medicine, and associate gynecologist, Mount Sinai Hospital, Philadelphia Second edition revised and enlarged 8°, cloth, 570 pp., with 133 illustrations New York Paul B. Hoeber, Incorporated 1946 \$7 50

Radiology for Medical Students By Fred J. Hodges, M.D. professor and chairman, Department of Roentgenology University of Michigan Medical School, Isadore Lampe M.D., associate professor, Department of Roentgenology University of Michigan Medical School, and John F. Holt M.D., assistant professor, Department of Roentgenology University of Michigan Medical School 8°, cloth, 424 pp., with 103 plates Chicago Year Book Publishers, Incorporated, 1947 \$6 75

Adolescent Sterility A study in the comparative physiology of the infecundity of the adolescent organism in mammals and man By M. F. Ashley Montague, associate professor of anatomy, Hahnemann Medical College and Hospital, Philadelphia, and visiting lecturer, Department of Sociology, Harvard University 8°, cloth, 148 pp., with 33 tables Springfield, Illinois Charles C Thomas, 1946 \$3 50

Penicillin in Syphilis By Joseph E. Moore, M.D., associate professor of medicine and adjunct professor of public-health administration, Johns Hopkins University School of Medicine, physician-in-charge, Syphilis Division of the Medical Clinic, and visiting physician, Johns Hopkins Hospital, chairman, Syphilis Study Section, National Institute of Health, United States Public Health Service, and chairman, Subcommittee on Venereal Diseases, National Research Council 8°, cloth, 319 pp., with 57 illustrations and 52 tables Springfield, Illinois Charles C Thomas, 1946 \$5 00

Military Neuropsychiatry Proceedings of the Association for Research in Nervous and Mental Diseases Volume XXV 8°, cloth, 366 pp. Baltimore Williams and Wilkins Company, 1946 \$6 00

Postgraduate Obstetrics By William F. Mengert, professor and chairman, Department of Obstetrics and Gynecology, Southwestern Medical College, and chairman, Obstetrics and Gynecology, Parkland Hospital, Dallas, Texas 8°, cloth, 392 pp., with 123 illustrations New York Paul B. Hoeber, Incorporated, 1946 \$5 00

Uterine Contractility in Pregnancy A study of the contractions of pregnancy and labor under normal and experimental conditions By Douglas P. Murphy, M.D., assistant professor of obstetrics and gynecology and research associate in the Gynececan Hospital Institute of Gynecologic Research, University of Pennsylvania School of Medicine 4°, cloth, 134 pp., with 64 illustrations Philadelphia J. B. Lippincott Company, 1946 \$5 00

NOTICES

RESIDENCY IN RADIOLOGY

Applications will be considered for appointment to a residency in radiology at the Joseph H. Pratt Diagnostic Hospital and Boston Dispensary from physicians with one or two years of training in radiology. There are about 1800 diagnostic cases monthly, as well as a tumor clinic and therapy and teaching conferences. Appointments will be made for one year beginning September 1, 1947.

Applications should be addressed to Mr. Richard T. Viguers, administrator, Joseph H. Pratt Diagnostic Hospital, 30 Bennet Street, Boston 11.

SOUTH END MEDICAL CLUB

The next regular meeting of the South End Medical Club will be held at the Prendergast Preventorium, 1000 Harvard Street, Mattapan, on Tuesday, June 24, at twelve noon. Dr. Eli Friedman will speak on the subject "Some Interesting Problems in Pediatrics."

This meeting will mark the twentieth anniversary of the Club.

(Notices continued on page xix)

mouth until there is stabilization of all labor at a more nearly normal level. We are greatly concerned, however, over the increasing demands for and the rising costs of nursing and over how these are to be met in the future. There must be and there is a solution to these needs, which can and will be worked out by a carefully planned and executed program and which has as its incentive one objective — the welfare of the patient rather than the continuation or extension of any existing patterns. Thus, there is much reason to believe that the present three years' training program leading to the R N degree is unnecessarily long and costly for preparing a young woman to carry out a large segment of bedside care, and that it is not adequate to develop a truly professional teaching and supervising personnel of high quality. Some breakdown, then, of our present concept of nursing care may be necessary. Just what pattern shall be followed may well depend on such experiments as are being carried out at present at the Massachusetts General Hospital, where a group of "earn-as-you-learn" hospital aids are being used under careful supervision for the routine bedside care of patients on two of the surgical wards. Possibly, as has been suggested, we should have three groups involved in our hospital nursing services: first and probably largest, young women and men trained for relatively short periods — probably not to exceed one year — to carry the burden of routine bedside care, secondly, young women and men with an adequate but not overscientific background trained to care for the more complicated and critically ill patients — a training that quite possibly might be condensed into less than the present three-year period, and finally, a group of truly professionally minded and trained young women, whose responsibilities will be the supervision of our wards, the development of nursing programs and the teaching of the nursing personnel at all levels.

It is believed by many that 60 per cent or more of bedside nursing can be done by young women and men with the relatively short period of training. Whereas the more complicated operations such as those on the thoracic viscera and the brain are being done in increasing numbers and require constant and skilled nursing, the care of routine general surgical patients (and, I suspect, of medical patients too) has been simplified, not complicated, by recent developments. What so many of these patients need for a few days is attention, not complicated professional care. If this is true and if, as many experienced physicians believe, the bulk of routine patient care can be done by young women after short periods of training, is it not conceivable that by lowering the over-all cost of caring for the uncomplicated hospital patients and increasing the coverage given to those critically ill, a concept of hospital care could be developed, the cost of which to the individual would be well below that of the present plan if one includes the almost routine use

of special-duty nurses, when they are available, in the early days following operation? But whatever method may be developed, surely at least a part of the high cost of hospital care must be met by a changing concept of what hospital service means to the patient seeking and paying for it.

An important, if not the most important, factor in the development and final success of any plan conceived and adopted by hospitals for the more efficient and less costly care of sick patients will depend on the interest and co-operation of the medical profession. Who, for example, shall decide whether a patient requires special attention or not? Surely not the hospital administration alone. You, the physician, better than anybody else know the condition of each patient, and extra services to those patients (exclusive of the luxury group) must be determined not on the wishes of patients or their families but on the condition of those patients in relation to the routine service that your hospital is able to give. Therefore, with the changing concept of what is best and most efficient for the care of our patients, let us take an active, aggressive and co-operative part in the development and execution of any constructive program that our hospitals may choose to establish.

Better routine care to the uncomplicated case with complete care to the seriously ill at the lowest possible cost that is spread among all patients entering the hospital in ward and semiprivate beds is, I believe, the objective toward which we should work.

But more inclusive and complete hospital service at the established rate is but a part of the answer. The over-all cost of good medical care will always be high, — too high for 84 per cent of the people of this Commonwealth to pay for out of pocket when the ax falls, — and it would be unfortunate indeed if any member of this Society failed to accept this as an integral part of his basic thinking. When you have accepted this, the inevitable question of compulsory versus voluntary coverage follows. There never has been and there is now no controversy between most of the proponents of the two methods over the objective, but there is complete divergence of opinion concerning the method by which that objective can most satisfactorily be reached. No one of you, nor I, nor anyone at this time has the vision to look into the future and say, "This or that is *the* method of paying for and distributing to the people of this country the highest possible quality of medical care." Whether we have voluntary or compulsory insurance will not of necessity depend on which is the better method but rather on what the people want. What the people want will depend on what proponents of a given method tell them as compared to how we as physicians lead and serve them. The proponents of compulsory insurance are now devoid of any favorable comparison. Medicine in England and Germany long ago ceased to favor it. Selective Service

established at such a level that they would approximate the cost of hospital care and suggested that in this community a rate of \$8 a day plus extras, or a total of about \$11 per day, be established as the minimum ward rate, with the understanding that those unable to pay the established rate be admitted as before for whatever they could pay. These rates were promptly accepted by most of the hospitals in the Boston area. If special nursing and professional fees are added to the \$11 or more a day and it is considered that in 1942, when earnings

fees used for this purpose. The results of these investigations benefit all prospective patients, not only in the hospitals in which the work is done but also in and out of all hospitals everywhere. The organization and execution of this work is the responsibility of teaching hospitals with adequate and well organized personnel and physical facilities. The financial responsibility in the past has been almost wholly assumed by private benefactors. Ideal as it is, this source is uncertain and is becoming more and more limited. Additional, more dependable sources (including federal funds) must be and are being sought and obtained. Although such money may well be given for a specific project, these grants should and must be complete and free from all obligations—moral or otherwise. At the same time, it is incumbent on these institutions to review their organizations and to be in a position to assure prospective donors that money so received is being used with the greatest possible efficiency—lest too much of what is available go into reduplication of effort, disorganized investigation and ill conceived and overlapping laboratory expenditures. Research well organized and efficiently done must continue to develop for the benefit but not at the expense of the sick patient alone.

Patient care, on the other hand, is the responsibility of the persons requiring hospital care and of the communities in which they live. If this is true and if in the future our voluntary private hospitals are to be supported by those who use them, is it not proper to ask whether or not our present hospital services are economical, efficient and a pattern to follow in future planning? In other words, what are the responsibilities of the hospital to the patients it accepts and now charges full payment for services rendered? Where do special nurses at \$25 or more a day fit into a program of such hospital care? Should they continue to be desirable for most patients undergoing routine major operations, even though in many of these cases their value to the patient and to the surgeon is in the constant attention to simple details in contrast to the experience, training and skill essential to the care of the more complicated conditions and the critically ill patients? Should special-duty nurses, as we now know them, offer a purely luxury service, except in cases in which they are assigned and paid for by the hospital to give the complete coverage that is necessary for the more seriously ill patients? Has not the time come when our concept of hospital service to the patients in semiprivate and ward accommodations requires careful and thorough revision and the adoption of a long-range program that will spread the cost of this care, regardless of the amount involved, over all patients entering the hospital?

The present shortage of nursing care is not pertinent to this discussion. It is here today as it was after the last war, and there is no immediate solution to it. We shall continue to live from hand to

FIGURE 1 Net Incomes by Classes for Massachusetts, 1942 (from Statistics of Income for 1942, compiled by United States Treasury Department)

were up, 69 per cent of the wage earners of Massachusetts had a net income of \$2000 or less and 84 per cent received less than \$3000 a year, it becomes at once obvious that the phrase "regardless of financial status" assumes real significance.

Let us for a moment consider the present high cost of hospital care. This is highest in our large teaching hospitals largely because of the overhead associated with research and other activities intimately tied up with medical advances and the teaching program. To eliminate these activities is to strike at the soul of good teaching and medical progress and is not to be considered. Still this is extremely costly. How can these institutions continue to meet the costs? Surely not by raising the charges for hospital service to the relatively few private patients cared for in these hospitals, nor should the same patients be expected to pay for it indirectly by having a portion of the professional

and that there is substitution of all labor at a reasonably normal level. We are greatly concerned over the increasing demands for and the increasing cost of nursing and over how these are to be met in the future. There must be and there is a substitution of personnel which can and will be worked out in a carefully planned and executed program and such as its incentive and objective — the welfare of the patient rather than the continuation of personnel of any existing patterns. Thus, there is no reason to believe that the present three years' training program leading to the R.N. degree is unnecessarily long and costly for preparing a young woman to carry out a large segment of bedside care, and that it is not adequate to develop a truly professional training and supervising personnel of high caliber. Some breakdown, then, of our present concept of nursing care may be necessary. Just what pattern shall be followed may well depend on such experiments as are being carried out at present at the Massachusetts General Hospital, where a group of "learn-to-learn" hospital aides are being used under careful supervision for the routine bedside care of patients on two of the surgical wards. Thus, there is much reason to believe that the present three years' training program leading to the R N degree is unnecessarily long and costly for preparing a young woman to carry out a large segment of bedside care, and that it is not adequate to develop a truly professional teaching and supervising personnel of high quality. Some breakdown, then, of our present concept of nursing care may be necessary. Just what pattern shall be followed may well depend on such experiments as are being carried out at present at the Massachusetts General Hospital, where a group of "earn-as-you-learn" hospital aids are being used under careful supervision for the routine bedside care of patients on two of the surgical wards. Possibly, as has been suggested, we should have three groups involved in our hospital nursing services: first and probably largest, young women and men trained for relatively short periods — probably not to exceed one year — to carry the burden of routine bedside care; secondly, young women and men with an adequate but not overscientific background trained to care for the more complicated and critically ill patients — a training that quite possibly might be condensed into less than the present three-year period; and finally, a group of truly professionally minded and trained young women, whose responsibilities will be the supervision of our wards, the development of nursing programs and the teaching of the nursing personnel at all levels.

It is believed by many that 60 per cent or more of bedside nursing can be done by young women and men with the relatively short period of training. Whereas the more complicated operations such as those on the thoracic viscera and the brain are being done in increasing numbers and require constant and skilled nursing, the care of routine general surgical patients (and, I suspect, of medical patients too) has been simplified, not complicated, by recent developments. What so many of these patients need for a few days is attention, not complicated professional care. If this is true and if, as many experienced physicians believe, the bulk of routine patient care can be done by young women after short periods of training, is it not conceivable that by lowering the over-all cost of caring for the uncomplicated hospital patients and increasing the coverage given to those critically ill, a concept of hospital care could be developed, the cost of which to the individual would be well below that of the present plan if one includes the almost routine use

of special-duty nurses, when they are available, in the early days following operation? But whatever method may be developed, surely at least a part of the high cost of hospital care must be met by a changing concept of what hospital service means to the patient seeking and paying for it.

An important, if not the most important, factor in the development and final success of any plan conceived and adopted by hospitals for the more efficient and less costly care of sick patients will depend on the interest and co-operation of the medical profession. Who, for example, shall decide whether a patient requires special attention or not? Surely not the hospital administration alone. You, the physician, better than anybody else know the condition of each patient, and extra services to those patients (exclusive of the luxury group) must be determined not on the wishes of patients or their families but on the condition of those patients in relation to the routine service that your hospital is able to give. Therefore, with the changing concept of what is best and most efficient for the care of our patients, let us take an active, aggressive and co-operative part in the development and execution of any constructive program that our hospitals may choose to establish.

Better routine care to the uncomplicated case with complete care to the seriously ill at the lowest possible cost that is spread among all patients entering the hospital in ward and semiprivate beds is, I believe, the objective toward which we should work.

But more inclusive and complete hospital service at the established rate is but a part of the answer. The over-all cost of good medical care will always be high, — too high for 84 per cent of the people of this Commonwealth to pay for out of pocket when the ax falls, — and it would be unfortunate indeed if any member of this Society failed to accept this as an integral part of his basic thinking. When you have accepted this, the inevitable question of compulsory versus voluntary coverage follows. There never has been and there is now no controversy between most of the proponents of the two methods over the objective, but there is complete divergence of opinion concerning the method by which that objective can most satisfactorily be reached. No one of you, nor I, nor anyone at this time has the vision to look into the future and say, "This or that is *the* method of paying for and distributing to the people of this country the highest possible quality of medical care." Whether we have voluntary or compulsory insurance will not of necessity depend on which is the better method but rather on what the people want. What the people want will depend on what proponents of a given method tell them as compared to how we as physicians lead and serve them. The proponents of compulsory insurance are now devoid of any favorable comparison. Medicine in England and Germany long ago ceased to favor it. Selective Service

statistics have been debunked. The United States Public Health Service, long cited as a Government agency efficiently run and free from any political pressure, fell from grace when each of its officers, including those in the Reserve,² was instructed by the Surgeon General of the Service³ to familiarize himself with the President's message (September 6, 1945) and to be guided by its provisions in any "public statement likely to be interpreted as representing the official views of the Public Health Service." And the public school, so often referred to as representing a form of taxation effectively returned to the people as public education, is no longer pointed to as an example of the efficiency and flexibility with which Government meets changing economic conditions. Devoid, then, of examples, the proponents must depend on theory, organization, propaganda and promises. But do not underestimate the logic of compulsory health insurance. In theory, on paper or over the air, it has everything. You and I, as practicing physicians, know that the problem is anything but as simple as Mr. Falk, Senator Pepper and others would have us believe. Not only do we as a group deliver to the people of this Commonwealth the greater part of their medical care, but also we, better than anyone else, know the problems. We know what keeps us on telephone call and what gets us out in the middle of the night, as well as what the people want, need and have a right to expect of their doctor. If this is true, should it not be possible for us to do our job as physicians and, in addition, to convince the people we serve, not only by valid argument but also by the effectiveness and sincerity of our efforts in their behalf? Are we not, by example, in a better position to reach the people of our community than those who must depend on words and promises alone?

We can be grateful to the Council of the Society for its wisdom and foresight in setting up the medical-care program as expressed through the Blue Shield. It is gratifying to learn that two million, or 50 per cent, of the residents of Massachusetts are now enrolled in Blue Cross and that Blue Shield had increased its membership by 108 per cent from January 1, 1946, to January 1, 1947. Both are to be congratulated on their rapid growth and their new comprehensive plans, effective on June 1, 1947, whereas there are some controversial points in the new Blue Cross coverage, these can and will be satisfactorily adjusted. It might not be amiss, however, to remind the directors of these services that they are a necessity for 84 per cent of the wage earners of this Commonwealth, but only a convenience to the remaining 16 per cent, and that any pressure from or desire to increase the appeal to the latter must not result in excessive cost to those they have been created to serve. These services must continue to grow and develop. Unless we as physicians have constantly before us the best interests of the people of Massachusetts

and do our utmost individually and collectively to make possible better and better care through individual efforts and an aggressive, co-operative medical-care program, we shall have failed not only in our duty but also in our opportunity. The time is past when any but the well-to-do can pay for a serious hospital illness when or after sickness occurs. Prepayment for hospital and medical care for the people of this Commonwealth is here to remain. Whether it continues to expand and progress and to develop on a voluntary basis with its many possibilities or whether it is ultimately placed on a compulsory basis with its inefficiency and governmental regulation is up to us.

Regardless of Financial Status

There is a large group in this, as in every state, who can pay for little or no part of its medical care. It will vary in size, depending on economic conditions and other factors. This is a large and an important group, and provision for its care is, according to our principles, the responsibility of the local or state government with the help of charitable agencies and if necessary federal grants-in-aid to state programs. Many are honest, frugal people who pay their normal way but have no savings or no prospects for meeting abnormal expenses. Others have never met and will never meet any obligations. A medical-care program that does not include this group is not complete and will not permanently survive.

Every Known Essential Preventive Diagnostic and Curative Medical Service of High Quality

Prevention of disease is the first fundamental of good medical care. The Commonwealth is favored with a public-health department of unusually high quality. To Massachusetts in 1869 went the honor of establishing the first state department of health in this country. In spite of its seventy-eight years of progress and its excellent record, however, over half the citizens of the Commonwealth are deprived of the benefits of the latest developments of medical science and preventive medicine.⁴ Until all the communities in the Commonwealth are covered with full-time medical health officers with special training in public-health work, until such men are given adequate compensation and until there is real co-ordination in all the public-health work of the Commonwealth at both state and local levels, preventive medical service of high quality will not be available to all the people of Massachusetts.*

Diagnostic and curative medical care go hand in hand. Far too much has been said in recent years about the cost and distribution of medical care, and much too little about the quality of services given. Both are important. Both must be developed. But unless the quality of service given

*Every member of the Society is urged to read the excellent survey of the program of the Department of Health referred to above.

is constantly improved, its distribution and the methods of paying for it are of little significance. You and I, who in the past have thought largely in terms of doing our daily work to the best of our ability, must now give thought not only to our patients but also to the organization and the development of our hospital and professional facilities to provide medical services of higher and higher quality, as well as to the development of organizations that make these services available to all the people of our communities. Fewer patients should come to our larger cities for care that can and should be given in their own community.

What, then, are the most important factors in a medical-care program whose object is to offer to a given community the best possible medical service, and what are our responsibilities as physicians in the development and utilization of these various factors?

A modern hospital of adequate size with an active, effective and co-operative governing board and an able, well organized professional staff are essential for a medical-care program of high quality.

Completely to fulfill its place in the community, the hospital must be the center of health activities. It is not enough that this hospital is of modern construction, well equipped and soundly financed. It must, in addition, be of sufficient size, preferably two hundred beds or more, although in many communities excellent, if more limited, medical and surgical services are being offered in smaller units. With few exceptions, however, hospitals with less than two hundred beds are dependent on larger institutions or outside personnel for many of the services essential to diagnosis and treatment of even the more frequent conditions. Also, the smaller the hospital, the more limited the staff and its clinical experience.

It has been suggested that a hospital of approximately two hundred beds can be efficiently maintained and offers sufficient clinical and laboratory material to assure well trained full-time radiologic, pathological and laboratory personnel. Moreover, the number of patients cared for is adequate to attract young men of ability and with proper training to assure a professional staff of high quality. I see little justification for the erection of general hospitals of fewer than two hundred beds except in rural areas, of which in this Commonwealth there are relatively few. How much better to follow the lead of the people of Newton and Wellesley and have adjacent communities join in the erection and maintenance of a plant of adequate size to be completely self-supporting and self-sustaining!

The trustees or governing bodies of our hospitals have a broader responsibility than the building and maintaining of the physical plant. One may well ask whether or not such a board is justified in urging a community to raise a large sum of money to erect and equip a modern hospital unless it is

prepared to support, to encourage or, if necessary, to insist on the development of a staff organization that will assure a quality of care in keeping with the institution to be built and supported. There is too often lack of co-operation between the trustees and the professional staff. Only by continued exposure of each to the problems of the other can there be proper understanding. Without this, no lay person, no matter what his interests, can appreciate the many practical problems of the physician in the care of his patients, and only by a better understanding and closer co-operation between trustees and staff will it be possible for modern hospitals to function with their greatest efficiency.

Given proper facilities in which to work and a responsible, co-operative governing board, the quality of medical care is dependent on — in fact, is — the complete responsibility of the medical staff. We share with no one the training and experience necessary to develop for the people of our communities the high type of medical care to which they are entitled. Our American way of free enterprise has placed high award on individual initiative. Medicine, by its very nature, has encouraged in every way the development of the individual instincts in all of us. No one can ever criticize the great mass of American physicians for any lack of personal application to their professional work. But the many advances in medical knowledge and the increasing complexity of medical care require more than individual application if patients are to be assured of the best possible care. Medical care of high quality is the end product of combined and well co-ordinated efforts. It has as its objective the welfare of the community as a whole, as well as of the individuals within the community. What is for their benefit will prove to be to our interests. It is no longer possible for anyone — no matter how capable, well trained or conscientious — to give complete medical care to any segment of his community, nor is it necessary that he try in so enlightened a state as ours. The co-ordination of individual efforts through group organization or within the well organized staffs of our community hospitals is, then, the guide to our professional development.

In the great proving ground of America, group medical care of every kind has been highly developed and is being successfully carried out. It remains for us in our various communities to select and develop the particular type that best suits our needs. Whatever the pattern, whether it be as a closely organized specialty group as exemplified in this community by the Lahey Clinic, or whether it be the more frequent, loosely knit organization of the entire professional staff around its hospital, as probably most highly developed in the Commonwealth at the Baker Memorial Hospital, there are certain requirements that are essential. It must offer the development of major and, when possible,

minor specialties, with the head of each department certificated by his respective board, recognition of and encouragement to general practitioners (except in certain specialty and teaching hospitals), assurance of a continuing high quality of care through the institution and development of a teaching program, and facilities for and frequent use of unrestricted consultations

The development of an effective staff organization (and for the moment I will restrict my comments to the surgical staff) that will attract well trained young men to our communities, assure them of an opportunity to develop and co-operate in the medical-care program and utilize the established personnel but at the same time develop a spirit of pride in and loyalty to the hospital and through it to the people of the community, rather than one of ownership in and jealousy of the hospital privileges that they enjoy, is a truly challenging responsibility. The people of this Commonwealth owe much to the hundreds of excellent surgeons who have learned surgery by long and continued application over the hard road of experience. Without them, surgery could not possibly have developed to its present high standard, and thousands of people in this Commonwealth would have been denied the relief that has been theirs through the untiring work of these men. But the advances in surgery over the twenty-eight years that I have been a member of this Society beggar our imagination. No body cavity, no viscus, is exempt from safe surgical approach. Resections of the stomach, colon or rectum are now carried out by our senior resident staff with a competence and safety that even ten years ago we should have thought neither practical nor possible. These advances have not just appeared. They are the result of continuous study and application of men in our teaching hospitals and their laboratories in co-operation with the laboratories of our medical schools. There have evolved new principles and a more thorough understanding of the old. Surgery has become too complicated, too all-inclusive for a young man to learn as a part of his daily medical practice or solely by association with an older man. The surgeon of tomorrow will be trained in the larger teaching hospitals of today and in the institutions that are developed tomorrow. Only by continued study and limitation of all his thoughts and efforts to the work of his choice can the surgeon of the coming generation expect and receive recognition by the governing boards of the hospitals in our larger communities. This generation of surgeons must be carefully trained in our hospitals under experienced supervision. Only in recent years have any of our hospitals, even the large teaching institutions in Boston, given sufficient training to qualify their graduates to do surgery in their own right. This is now being well done in many of our larger teaching hospitals throughout the country, but more opportunities are needed for

young men anxious to give time and effort for a sound surgical training. The development of proper staff organization in the larger general hospitals of this Commonwealth not only will offer more opportunities for a new generation of surgeons but also will assure the patients in those hospitals of the high quality of professional care that goes with a resident program.

Organization of the hospital staff into the several specialties, each headed by a man certificated by the specialty board, interested in and willing to give enough of his time and effort to the development of his department, restriction of staff members to those limiting their work to their own specialty and the establishment of a merit system whereby appointments to and promotion of the staff are made on a basis of ability and application rather than seniority are the first steps in assuring professional care of the highest possible quality and to the later introduction of a resident program. I should add that, at least for the present, I consider it neither necessary nor desirable for a hospital to require that all its staff members be either certificated by their specialty boards or that those on the surgical staff be fellows of the American College of Surgeons. Insistence on these credentials will not in itself assure good care and is certain to prove a hardship to many able men who by years of application are capable of and are doing excellent work in their communities. Ability, application and a progressive and active interest in the continued development of the medical-care program rather than diplomas on the wall should be the basis for appointment to the staff of our community hospitals. I do believe, however, that all heads of departments and men holding senior staff positions should be certificated by their boards and that the surgeons in more responsible positions should be fellows of the American College of Surgeons.

Any staff organization that does not recognize and include the general practitioners of the community that the hospital serves is not giving full service to that community. There are those who have said that the days of the general practitioner are gone, but the general practitioner has been, is now and will continue to be the real backbone of our medical-care program. The American Medical Association has recognized this in the establishment of a Section of General Practice, and it is probably only a matter of a short time before there will be a specialty board to certificate men in general practice as well as men in the various specialties. They are an intimate part of medical care in any community and must therefore be an active part of the staff organization of all except the highly specialized or the large teaching hospitals.

Closely associated with the staff organization is the development of a teaching program without which no hospital staff can continue to fulfill its complete obligations to the community. Teaching at

some level is possible in every well organized institution. Teaching will be most effectively done and at its best if there are active young minds attached to the hospital as part of a training program. Even without interns or residents, however, hospital clinics, clinicopathological exercises and other scientific programs can and must go on continuously to stimulate the thinking and reading of the staff members and to assure to all patients of the community the benefits of the newer trends in medicine.

What about research? Let us never forget that all medical education and all investigative work have as their ultimate objective the improvement of the medical care of people who need it. Unless new discoveries can find clinical application, they are of little or no importance. One of the really great problems in American medicine lies in the practical application of what we learn to the people of the communities we serve. The possibilities for real constructive advances in the development of medical services in the hospitals of this Commonwealth are almost limitless. That many of even the common medical and surgical cases still come to our larger cities is a natural result of the concentration of the more highly trained internists and surgeons in those areas. As more young men are well trained in the various specialties, however, the trend in medical care for all but the more complicated conditions must be from our larger metropolitan teaching centers back to the communities in which the patients live. The opportunities for men with imagination to develop sound, workable programs in our community hospitals that will make this possible offers a challenge equal to that of the teaching hospital and its laboratories.

Probably one of the most important contributions of good staff organization and co-operation comes from the free exchange of knowledge through frequent use of consultations. These consultations, to be truly effective, must be unrestricted and must make use of any member of the hospital staff, or if necessary of the staff of a neighboring hospital, who can give the greatest help toward the solution of a given patient's problem. In no small degree, the excellence of care given in any one of our hospitals is reflected in the degree to which the consultation service utilizes the knowledge and experience of the entire professional and laboratory staff.

Available to Everyone — Regardless of Race, Color, Creed, Financial Status or Place of Residence — Every Known Essential Preventive, Diagnostic and Curative Medical Service of High Quality

To make medical care available to all the people of the Commonwealth, 84 per cent of whose net

weekly income is below \$60, when the cost of a ward or semiprivate bed in a Boston hospital (exclusive of the cost of special nurses and professional care) varies from \$80 to \$90 a week, is a challenging undertaking. In addition to a mechanism of providing for those who cannot pay for themselves and of obtaining more complete prepayment coverage of the remainder of this group, careful re-evaluation of our present pattern of hospital care should be undertaken so that when economic conditions permit, hospital services may be altered to allow complete coverage to the patient in a ward or semiaccommodation at the lowest possible cost to the hospital and patient, with this cost shared by all patients, whether actual or potential recipients of total service, and paid for through membership in a voluntary prepayment plan. Accomplishment of this goal can be possible only if there is thoughtful, aggressive, co-operative effort of the public, the medical profession, the hospital and nursing authorities, our voluntary medical and hospital services, our charitable agencies and the local and state government units.

To assure continuing improvement of the quality of medical care requires additional effort by and co-operation between hospital governing boards and the professional staff. A well run hospital of adequate size with an effective staff organization, a teaching program and finally the development of resident training will offer to its community a quality of service of which it can be justly proud.

You and I have the good fortune to live at a time and in a state when what should be can be — but only if we as individuals as well as a society offer the active far-sighted leadership and the co-operation with other agencies that are so essential to success.

The attainment of such medical care must necessarily be an evolutionary process which will require the co-operation of all concerned over a period of years.

Addendum I am indebted to those innumerable and stimulating committee meetings, conferences, personal discussions and communications from which I have learned and to which I owe so much.

THROMBOPHLEBITIS—THE PROBLEM OF TREATMENT*

HOLLIS L. ALBRIGHT, M.D.†

BOSTON

MUCH has been done by members of the New England Surgical Society and their associates leading to greater understanding of thromboembolism. A recent thorough and searching review by Homans¹ is classic in its contribution both to the student and to the clinician responsible to his patient. In the light of this and with exceeding deference, some of the problems arising in the approach to the patient with acute thrombosis of the deep veins of the extremities are discussed. The widespread consideration of this problem from many points of view attests to the uncertainty concerning any single most effective method of treatment.

There is general agreement regarding vigorous prophylaxis to maintain muscular tone and circulatory efficiency. Ochsner² stops his patients from smoking ten days before operation, applies compression bandages from ankle to groin and routinely employs dry heat to the abdomen and not to the extremities, to lessen peripheral vasospasm. Gentle operative technic without overmanipulation of the viscera and avoidance of surgery during the menstrual period find general acceptance. Postoperative elevation of the foot of the bed for forty-eight hours has been favored to aid in emptying the veins of the extremities. Most surgeons encourage their patients to wiggle their toes a thousand times three times daily, to leg movements every three to five minutes and to bicycle exercises. Many practice early rising, which has been termed "early ambulation."

Early ambulation may prove to be helpful. It should not be permitted to prove harmful. Allowing especially the elderly or debilitated patient to sit with the legs hanging in a flaccid dependent position, crossed or uncrossed, is not early ambulation. It is my opinion that the postoperative patient should either walk upright or remain lying in bed, being allowed up in a chair only when he is able to walk to it. Exercise of the leg muscles should be practiced while the patient is sitting. An increase in the frequency of headache following spinal anesthesia has caused me usually to defer early rising until at least forty-eight hours after operation.

In the care of the patient with signs of obstructive deep phlebitis of the extremities, the risk of embolism, however slight, is recognized early. A feeling of increased resistance of the tissues has proved a helpful sign, along with slight swelling and Homans's dorsiflexion sign. Bauer,³ from a large experience, advises early phlebography as routine in

all cases of suspected thrombosis, on the vaguest chest or local signs. Suggestive chest signs of infarction, of course, increase the urgency of decision regarding the method of treatment.

Little reliance should be placed on any attempt to differentiate a nonadherent and an adherent clot. Both have been observed in the same vein on several occasions. In 5 patients with femoroiliac thrombosis an adherent femoral thrombus, with proximal nonadherent grape-jelly clot in the iliac veins, was observed.

Most authorities agree that early and frequent use of sympathetic blocks with novocain throughout the period of pain, tenderness, fever and swelling may prove helpful. Injection of 10 cc of 1 per cent novocain into the region of the first, second, third and fourth lumbar sympathetic ganglions unilaterally or bilaterally has been employed, 100 cc of 1 per cent novocain being recognized as the accepted toxic dose. Tulane's young graduates practiced this with frequency in Army wards, as a result of Ochsner's insistence that every student be familiar with the indications for and easy execution of this as a ward procedure.

Decision should be made early—within the first twenty-four hours—concerning the major course of treatment, whether anticoagulants or proximal-vein ligation, or both, are employed. Attention should then be directed to the possibly helpful use of adjuvant measures, not only to safeguard against embolism but also to protect the collateral channels against spread of the thrombophlebitic process. A cradle with a light over the abdomen, abstention from smoking and sympathetic novocain blocks on the obstructed side, in addition to the equivocal effect of papaverine, may lessen vasospasm. Early exercise and post-ligation use of heparin or dicoumarol may further aid in quicker subsidence of the inflammatory process and may lessen the late effect on circulatory efficiency. Smithwick⁴ has suggested that in his experience sympathetic novocain block in the heparinized patient seems to produce increased effect.

If anticoagulant therapy is decided on, in the light of many published favorable experiences with both heparin and dicoumarol,^{5,6} certain facts should be kept in mind. Sustained vigilance of the unstable clotting times is essential for several days. With heparin the venous clotting time, checked twice daily to maintain an optimum time of between thirty and forty-five minutes, was observed to rise quickly to two and a half hours, fortunately with no ill effects. Both heparin and dicoumarol should be

*Presented at the annual meeting of the New England Surgical Society, Worcester, Massachusetts, October 4, 1946.

†Assistant professor of surgery, Boston University School of Medicine.

used with extreme care in wounds involving the cranial, pleural and abdominal cavities and in fractures encased in plaster. Hematuria and hemorrhage into joints have been reported as untoward effects.³ Heparin clears from the blood quickly, within two or three hours. Dicoumarol produces no effect on the clotting time until the prothrombin level has been reduced to 30 per cent of normal.⁶ It requires two or three days to become effective, and loses its effect on the prothrombin level slowly. Properly administered, both heparin and dicoumarol seem un-

done relatively late in the disease, — ten days to several weeks after battle injury, — required ligation of the common iliac vein on the involved side, with supplementary ligation of the superficial femoral vein on the apparently uninvolved side. The remaining 4 cases developed during the hospital stay. Chest symptoms and signs or x-ray findings suggestive of pulmonary infarction were present in 6 cases. Bilateral ligation was done in 5 cases, and unilateral in 4. Additional measures in conjunction with ligation were used too meagerly, in retrospect

FIGURE 1 *The Vertical Injection of Novocain about the Great Femoral Vessel*

doubtedly effective despite the still obscure mechanism of their control of the formed clot.

When ligation of the involved or suspected veins has been decided on, every effort should be made toward early ligation. This may avoid the more drastic ligations at higher levels and should reduce the real frequency and severity of postoperative swelling, which still limits somewhat the acceptance of this procedure.

In an experience with 8000 patients in a fixed Army general hospital in England during the eleven months from D Day (June 6, 1944) to VE Day (May 11, 1945), 9 patients were subjected to proximal ligations at levels higher than the superficial femoral vein. Interest was stimulated toward ligation as the safest method of control, not only on the basis of civilian experience but also on autopsy observation on 2 soldiers in whom embolus had plugged the pulmonary arteries, with a truncated adherent thrombus in the right internal iliac vein in one patient and in the left common femoral vein in the other.

All nine patients had demonstrable obstructive thrombophlebitis. Five operations, which were

Heparin was used intravenously in only 3 patients, and lumbar sympathetic blocks with novocain in 2.

Although caution should be emphasized in the impressions gained from a few cases in such young patients, ranging from nineteen to thirty-six years of age, it may be stated that no further pulmonary disturbances developed, no untoward results were noted (except for nonincapacitating edema in 2 patients), and all patients, both in and out of leg casts, were allowed out of bed much earlier than they would have been without ligation. Follow-up letters seventeen months after these studies have revealed no additional sequelae.

The anesthesia employed was local in 4 patients at the level of the common femoral vein, and general in the 5 cases of iliac ligation (spinal anesthesia in 3, and ether in 2).

Certain technical features of ligation seem worthy of mention. Signs of pulmonary infarction or of phlebitis of the pelvic veins impel one to ligate at the level of the common femoral and iliac vein or of the vena cava, respectively, with due regard for control of the veins of both extremities. These

high proximal ligations, however, should be less frequently necessary if early ligation of the superficial femoral vein, preferably bilateral, in combination with other helpful measures, is performed. With this in mind, attention will be directed toward

FIGURE 2 Isolation of the Superficial Femoral Vein. Exposure of the deep vessels is facilitated by preliminary retraction of the femoral artery. Care is taken to avoid injury to the great saphenous nerve. The profunda femoris vein is visualized.

the technical aspects of ligation of the superficial femoral veins.

Excellent results have been obtained with the use of local anesthesia for ligations below the inguinal ligament by the simple technic illustrated in Figure 1. After skin and subcutaneous infiltration with approximately 20 cc of 1 per cent novocain, 10 cc is injected through a needle inserted vertically to the level of the great vessels at a point overlying the fossa ovalis—that is, 2.5 cm lateral to and 1.5 cm below the anterosuperior spine. Careful aspiration guards against injection into a vessel. Usually, no further injection is required. This procedure has likewise proved eminently satisfactory for ligation of the saphenous vein and its tributaries.

An adequate, 8-cm longitudinal incision is made just medial to the pulsating femoral artery as a guide (Fig 2). Transverse incision may be extremely hazardous because of its restricted exposure at the level of the deep vessels and may interfere with the lymphatic drainage of the extremity. Generous exposure at the deep level is essential. The incision should not be allowed to become narrow and conical in depth, giving dangerously restricted exposure, especially when the perivascular inflammatory reaction is marked.

With retraction of the sartorius muscle laterally, care should be exercised against injury to the large saphenous nerve coursing in the fascia overlying Hunter's canal. This is the large terminal branch of the femoral nerve. Injury has not infrequently occurred, in my experience, producing disturbing hypesthesia along the inner lower thigh and leg areas.

There is nothing superficial about the superficial femoral vein. It lies not only medial to but also far below the femoral artery in Hunter's canal. It comes into view only when the femoral artery has been first exposed, carefully freed and retracted with soft rubber Penrose tubing. Because of the deep position of the vein the term "distal femoral" rather than

FIGURE 3 Removal of the Thrombus. Aspiration is continual until brisk retrograde flow is obtained. The distal vein segment is later aspirated.

"superficial femoral" vein has seemed more accurately descriptive.

Before a clamp is passed beneath the superficial femoral vein, the deep tributaries arising from the posterior aspect of the vein—namely, the profunda femoris and the large muscular branches—should be visualized. Failure to do this in one patient led to alarming deep hemorrhage, unrecognized damage to the femoral artery and mid thigh amputation for gangrene seven days later. In an additional patient with restricted operative exposure, the damaged portion of the femoral artery required resection, followed by anastomosis and immediate heparinization. This resulted fortunately in a successful outcome.

Isolation of the femoral vein just distal to the profunda femoris vein (Fig 3) prepares the vein for partial transection and gentle catheter or glass-tube aspiration of all proximal clot until brisk retrograde flow is obtained. It is my practice to

explore the profunda femoris vein with a hypodermic needle to aid in deciding whether to ligate proximal or distal to the profunda femoris vein. Additionally, ligation at the lower level is regarded as inadequate if there is proximal, adherent, fragmented thrombus that is removed with difficulty.

After brisk retrograde flow has been obtained and the proximal vein segment secured, aspiration of the distal vein segment is carried out before complete section and transfixion of the vein. It has been my impression that subsidence of the local thrombophlebitic reaction has thereby been encouraged.

FIGURE 4 *An Organized Floating Thrombus*

Postoperatively, elastic bandages are applied from ankle to groin, and the patient is allowed out of bed as soon as his physical condition permits.

Figure 4 shows a nonadherent, organized thrombus 8 cm in length, removed from the right common femoral vein of a thirty-six-year-old infantry sergeant. The patient had sustained multiple battle wounds thirty-two days previously, including a compound fracture of the right tibia. Unexplained pain in the left side of the chest for thirty hours had been noted. X-ray films of the chest were unrevealing. There was slight tenderness over the femoral vein in the fractured leg. When the vein was opened there was brisk, apparently normal flow of blood as the midportion of the torpedo-shaped thrombus presented itself for easy removal. Recovery was uneventful.

Finally, in addition to vigorous prophylactic measures, it may prove wise in certain cases to ligate the superficial femoral veins bilaterally prior to a planned operation or long illness. Rigidly controlled indications for this should be well understood.

* * *

An ever-alert approach to the confined patient with emphasis on prophylaxis, early recognition and treatment with either anticoagulants or proximal ligation, or both, should offer the patient a large degree of protection against thromboembolism. It is toward the control of pulmonary embolism without warning, however, that preliminary ligation is largely directed.

In addition to early ligation distal to the profunda femoris vein, combined use of sympathetic blocks, heparin or dicoumarol and early rising should offer greater protection than ligation alone, not only

against thromboembolism but also against damage to the collateral vessels. Both vasospasm and obliterative endophlebitis spreading to the indispensable collateral vessels may thus be lessened. Judicious employment of a combination of helpful procedures, rather than any single procedure, may offer greater protection to the patient. Disturbing sequelae should be lessened, and the more drastic higher ligations less often necessary.

DISCUSSION

Dr. JOHN HOMANS (Boston). Dr. Albright has covered a good deal of ground with a great deal of intelligence and common sense. It is rather difficult to find fault with anything he has said about thrombophlebitis. I am perfectly certain that he has a comprehensive understanding of it.

It seems to me that if I were to criticize, in a friendly way, his presentation, I should say that he had drawn a good many conclusions from his military experience, if I understand him correctly, in the surgery of these youngish patients. I have previously heard discussion of the matter of thrombosis in such patients, and apparently when the man of military age suffers a thrombosis he tends to become extremely thrombophilic, the ordinary methods of handling this thrombosing process seem to work in different ways from those of older persons. I have heard of a good many vena-cava ligations and so forth.

Actually, I find myself more interested in these days in the problem of thrombosis in cardiac and medical patients who really offer a continuing problem, because they are confined to bed with serious disease and the matter of preventing them from having thrombosis and embolism is quite a different one from what it would be in younger persons — for instance, those who have suffered accidents or have been operated on.

I suppose one must decide, as I am sure the Massachusetts General Hospital group have decided, that there are certain cases that can be handled in no other way than by prophylactic vein division — for example, patients who must be operated on for serious abdominal diseases. Such patients, and probably some of the cardiac patients as well, can evidently be subjected to a superficial femoral division with a great deal of satisfaction.

The Swedes have an interesting idea of trying to prevent thrombosis from rising above the knee — above the popliteal vein — on the ground that once the thrombosis reaches the femoral vein, that vein will be crippled and the future of the leg will present quite a serious problem. They have therefore decided to try to make an early diagnosis under the usual circumstances in which thrombosis is likely to arise. Then they attempt to prevent the progress of the process by the use of anticoagulants. In a way, that is a more reasonable approach to the subject than the use of the division of the vein. And I must say that I am sympathetic with it.

I should like to go a little farther and say that in the occasional patient who suffers a thrombosis below the knee in everyday life the future is likely to be a great deal brighter if the process can be subdued by anticoagulants than if the femoral vein is divided. The question is whether there is an equal amount of safety in the two procedures. I am still utterly uncertain about that point, but having divided a good many veins in persons with fairly extensive thrombosis that has probably not already crippled the superficial femoral vein, I should rather not divide a femoral vein if I can stop the process from rising to the level of the groin by the use of anticoagulants. That is a point of view that Dr. Albright

did not present. I should like to hear his opinion about it.

His system of operating on patients who already have a fairly extensive process, I think, is ideal. I do not like divisions of the common femoral vein above the profunda. If it is safe to remove the thrombus by opening of the femoral vein below the profunda and especially if afterward one can make use of anticoagulants, that seems a better way to handle the process.

I should like to have Dr Albright's view on the use of anticoagulants after division of the superficial femoral vein. I know that there are a great many other aspects of this subject. I have merely spoken of some that occurred to me as being among those that perhaps Dr Albright did not go into with great detail.

DR ARTHUR W ALLEN (Boston) I am amazed at how closely Dr Albright's paper follows my own views on the treatment of thrombophlebitis, and I should like to congratulate him on having presented it as well and as quickly as he did. In other words, I agree with him that we have three useful measures of treatment at our disposal, and quite often all three should be used.

I want to speak for a moment about the prophylaxis of thrombosis. I am quite sure that the future primarily holds for us the duty of preventing the patient from developing a thrombosis with a possible embolism. Patients in the young and middle age groups who do not have diseases that contraindicate the use of anticoagulants can safely be protected from thrombosis by a controlled, careful use of heparin and dicoumarol, but there is a limit to the number and the type of cases to which this can be applied.

The high incidence of thrombosis and embolism in older patients, particularly those with leg injuries, as Bauer, Veal and Homans have emphasized, is to be considered in a slightly different category.

In the treatment of thrombosis to prevent further embolism, we soon learned that we should interrupt both femoral veins. We were much interested to find that if we interrupted a normal femoral vein, symptoms such as swelling in the legs rarely occurred. This came as quite a surprise in spite of the fact that the femoral vein had formerly been interrupted in an effort to benefit the circulation in cases of thromboangitis obliterans. A short period of edema that did not always occur was expected, but I think that the significance of this did not register until we had experience with a great many hundred cases, in which it was found that if the vein was interrupted before thrombosis developed, the sequelae were negligible.

In 50 consecutive cases of fractures about the hip we have recently interrupted prophylactically the superficial femoral vein bilaterally. In none of those patients has an embolism occurred, and in none has any evidence of thrombosis appeared.

In the preceding 50 cases, which were exactly identical and did not have this prophylactic interruption, there were 5 proved fatal cases of pulmonary embolism, — a rate of 10 per cent, — and there were 2 additional patients who died similarly, probably from embolism, although no autopsy was performed.

We have now more than 450 patients in the older age group who would formerly have been treated in bed for one cause or another but who have had what we consider prophylactic femoral-vein interruption. In other words, interruption has been done shortly after the period of bed rest has been necessary and theoretically before any thrombosis has occurred. There has been only 1 case in which a fatal embolism later occurred. In that group we should have expected a great many deaths from embolism. There has only been 1 case of a mild thrombophlebitis below the knee, as well as a few cases of minor transient edema, but most of the patients showed no signs or symptoms from this adequate protection against thrombosis and embolism.

DR E EVERETT O'NEIL (Boston) Perhaps my opinion and my position are somewhat unfair, but some years ago when we first started using heparin and dicoumarol, we had an extremely unfavorable experience with the anticoagulants. For that reason we soon forsook our position in using them as a form of therapy and have subsequently adhered rigidly to the division of large veins as a measure of handling deep venous thrombosis.

Like Dr Homans we have in most cases practiced division of the superficial femoral vein, and for similar reasons. Our

experience with division of the deep femoral veins has not been good, because we have found that there have been many cases in which residual swelling has persisted for long periods, beyond what we have seen in division of the superficial femoral veins.

That is perhaps an academic matter, however. Nevertheless, the operation of dividing the superficial vein is slightly easier than dividing the common femoral, and perhaps lends itself more easily to practice by residents and house officers, who usually do the operation in the large hospitals.

So far as the anticoagulants are concerned, surgeons are interested in using some procedure that may guarantee before operation that venous thrombosis will not occur. Anticoagulants certainly cannot be used before operation, and there therefore is no guarantee that the patient will not die of embolism one or two days or even hours following the operation, because what has not been stressed by the proponents of anticoagulants is that thrombosis may be present long before operation has been started and, as I have suggested, lethal embolism may occur shortly thereafter. Therefore one must take the quickest measure of circumventing this catastrophe, and that, in my opinion, is division of the proper veins.

Our opinion of prophylactic venous divisions is similar to that of Dr Allen. More and more prophylactic venous divisions will be done in properly selected groups, which we know by experience lend themselves to venous thrombosis.

I think — and this fact should be emphasized — that when a normal femoral vein has been divided, swelling seldom if ever occurs, and that brings up the point that early diagnosis in deep femoral thrombosis is the *sine qua non* of success in the handling of these cases.

If the diagnosis is made early and the veins are tied early, not only will more lives be saved but also many of these complications, such as swelling, will be averted.

DR DONALD MUNRO (Boston) As a result of my experience and from listening to the paper and the discussions, I am confused regarding certain aspects of this problem. I gather from what has been said that it is considered important that patients be mobilized early — particularly the legs — to prevent the development of thrombosis and embolism and that in pursuance of that ideal, prophylactic ligation of the femoral veins has met with widespread approval.

I do not understand why patients that I see who have been paralyzed as a result of spinal-cord injuries, whose legs are certainly as immobile as possible and who lie in bed for months or often for years do not get femoral thrombosis or embolism even though the veins have not been ligated prophylactically or therapeutically.

I have rather detailed knowledge of about 250 such cases. Although I cannot give the exact figures, I do not believe that we have had any patient who died as a result of pulmonary embolism among this group, and I am sure that the incidence of femoral thrombosis is so low as to be negligible.

I have also less intimate knowledge of between 500 and 600 similar patients that I have seen in various Army hospitals. Two hundred of them I am quite familiar with. Certainly, femoral thrombosis and pulmonary embolism in those cases were so rare that in no hospital that I have visited has the question been raised whether there was any need to do anything to prevent such complications.

DR ALBRIGHT (closing) Regarding the use of anticoagulants to prevent progression of the clot from the leg to the femoral vein, it is difficult to pass judgment. Heparin in Pitkin menstruum may be employed, and I prefer that to dicoumarol. From recent experience, Dr E V Allen has stated that small doses of dicoumarol that reduce the prothrombin time slightly will not affect the coagulation time or the clot. There must be a reduction of the prothrombin time to 30 per cent or less. If it is between 30 and 100 per cent, no effect has been produced by the dicoumarol.

I have no objection, if one decides to use anticoagulants, to using them well and effectively. Pitkin solution of heparin can be given easily, in small subcutaneous doses, the effect lasting for two days, and controlled by venous clotting times. Dicoumarol requires two or three days to become effective, and if one wishes to stop it, its effect lasts an additional few days.

The anticoagulant may be started usually two days after ligation. Intravenous heparin clears from the blood within a few hours, and may be stopped if a bleeding tendency occurs.

In vascular surgery, especially in arterial anastomosis, heparin has frequently been used without untoward effect. In my experience bleeding occurred more frequently in large avulsed wounds, controlled by discontinuance of the heparin and pressure dressing.

I am quite conscious of the fact that these Army patients were young. My civilian patients have been largely in the group over forty years of age.

In patients with fractures as Dr. Allen pointed out, I believe that prophylactic ligation should be given proper consideration. Overseas, the wards were filled with patients in casts. It was extremely difficult to evaluate leg pain, fever and the question of venous tenderness by palpation under the edge of the cast at the groin or midhigh level. The decision whether the pain was caused by the regional swelling about the fracture, infection or thrombophlebitis proved a real problem. Consequently, several patients had chest signs before ligation was carried out.

Dr. O'Neil has emphasized the desirability and urgency of early ligation, with which most of us agree. Actually a certain number of patients are first seen in an advanced, late stage of thrombophlebitis requiring ligation at higher levels. This makes it difficult to lessen the incidence of postoperative disturbances, which tend to limit the acceptance of this procedure.

Dr. Munro wishes to know why his paralyzed patients do not get thrombosis or embolism. Because of the paralysis from the waist down, there is no factor of vasospasm or arteriolar spasm. Ochsner considers the element of vasospasm so important that he teaches his medical students to perform repeated lumbar sympathetic blocks with novocain, regardless of whether ligation is performed or heparin given. The absence of vasospasm in these young patients, who have excellent cardiovascular systems with efficient muscle and elastic vessel walls probably constitutes the chief explanation of the infrequent thrombi.

THE EFFECT OF RESTRICTED INTAKE OF CAROTENE AND VITAMIN A ON PSORIASIS VULGARIS*

A Preliminary Report

RICHARD HOFFMANN, M.D. † EVELYN J. LORENZEN, Ph.D., ‡ AND ARLENE S. GARFINKEL, B.A.

BOSTON

KNOWLEDGE concerning the etiology and pathophysiology of psoriasis vulgaris is limited. Certain characteristics of the disease are generally recognized, however. One of the main physiologic functions of the epidermis is the production of keratin necessary for the protection against and for the repair of injuries to the cutaneous system. In the skin of a psoriatic person the mechanism of keratinization fails whenever increased demands on the protective and reparative processes of the epidermis occur. Instead of completely keratinized cells, defectively cornified—that is, parakeratotic cells—are produced.¹⁻³ The extent and degree of the parakeratosis are related to the clinical activity of the psoriasis. In early stages the characteristic parakeratosis usually extends uniformly across the lesion, becoming even more uniform and greater in rapidly developing and progressing lesions. Quiescent and healing lesions show hyperkeratosis in place of or together with parakeratosis.⁴⁻⁶ Psoriasis rarely occurs in Negroes.⁷⁻¹⁰ This may be explained by the greater thickness of the stratum corneum of the skin in Negroes as compared with that of the skin in Whites,⁹ and by its greater resistance to external irritants.⁹⁻¹¹ Both properties oppose the establishment of psoriasis. Careful sun treatment, local application of tar, sulfur, chrysarobin and so forth and internal administration of inorganic arsenic compounds are widely recognized as beneficial agents in the treatment of psoriasis. Various factors are operative in the action of these remedies. They have in common, however, a distinct keratoplastic effect, which may be of importance in the correction of the defective keratinization.

A low-fat diet has likewise received favorable recognition in the treatment of psoriasis. Grütz

TABLE 1 Dietary Allowance of Foods Containing Vitamin A^{12, 13}

Foods†	Amount	Vitamin A Content international units

lowering of the fat content of the cutaneous elements was the basis of the beneficial effect. There has been considerable disagreement, however, regarding both the theoretical basis for this treatment and the findings of increased lipids in the serum and in the skin of psoriatic patients^{4, 8, 12-17}

Since a defect in the reactive process of keratinization appears to be an essential factor in the pathophysiology of psoriasis and since keratoplasia is observed in vitamin A deficiency,¹⁸⁻²⁰ it occurred to us that the improvement of psoriasis subsequent to the Grütz-Burger low-fat diet might be due

ated every two weeks by the dietitians of the Food Clinic. To ensure an adequate intake of other essential nutrients, supplements of vitamin B complex, ascorbic acid and iron were added to the diet in the majority of cases. Patients were specifically instructed to consume a sufficient amount of fats free of vitamin A to compensate for the omission of fats containing vitamin A. No local treatment except white vaseline was used.

Physical examinations were repeated at intervals of two to four weeks. Skin biopsies were examined microscopically in the majority of patients before

TABLE 2 *Effect of Diet Restricted in Carotene and Vitamin A*

to the simultaneous decrease in the supply of vitamin A. The purpose of this investigation is to observe the influence of a diet low in vitamin A on the clinical course of psoriasis.

PROCEDURE

Only patients who had had extensive psoriasis vulgaris of long duration without experiencing spontaneous remissions were studied. A maximal daily intake of 150 to 300 international units of vitamin A was allowed (Table 1). Foods containing more than 50 international units of vitamin A per average serving were prohibited whereas foods free of vitamin A were allowed in unlimited amounts. A record of the daily intake of each patient was evalu-

ated every two weeks by the dietitians of the Food Clinic. To ensure an adequate intake of other essential nutrients, supplements of vitamin B complex, ascorbic acid and iron were added to the diet in the majority of cases. Patients were specifically instructed to consume a sufficient amount of fats free of vitamin A to compensate for the omission of fats containing vitamin A. No local treatment except white vaseline was used.

Physical examinations were repeated at intervals of two to four weeks. Skin biopsies were examined microscopically in the majority of patients before the diet was begun and thereafter at intervals of three to six months.

Clinical supervision and the reports of the patients regarding adherence to the diet had to be relied on in the early stage of the investigation. At present, in conjunction with the clinical observations, the plasma carotene and vitamin A levels are determined periodically by the colorimetric method of Kimble.³² These data afford an objective measure of the patient's co-operation in adhering to the diet, an insight into the extent of the correlation between the clinical and biochemical changes and some assurance that a harmful degree of vitamin A deficiency has not developed.

OBSERVATIONS

In 9 of 11 cases the psoriatic lesions markedly improved or completely cleared within eight to forty weeks after the initiation of the diet restricted in both carotene and vitamin A (Table 2). The first definite signs of improvement appeared within four and twelve weeks. Since spontaneous amelioration is frequently experienced during the summer months,²⁴ improvement noted during the months of April to October was not considered significant.

within eight weeks after the initiation of a dietary regime restricted to 800 international units of vitamin A. No untoward effects were observed in any other patient.

In 6 patients who had shown marked improvement or complete clearing of the lesions, relapses occurred within three to eight weeks consequent to the resumption of a normal unlimited diet, and in 1 patient six weeks after supplementation of the restricted diet with carotene. Within two weeks after the carotene supplementation had been dis-

TABLE 2 (Continued)

CASE No	PLASMA CAROTENE CONTENT		PLASMA VITAMIN A CONTENT		RELAPSE
	RESTRICTED DIET	NORMAL DIET	RESTRICTED DIET	NORMAL DIET	
	microgm/100 cc	microgm/100 cc	microgm/100 cc	microgm/100 cc	
1	—	—	—	—	On daily vitamin A intake of 1500 international units only few nummular lesions on elbows and forearms after 8 wk. resumption of normal diet followed in 8 wk. by relapse; slight spreading during following year; no change in weight on diet.
2	—	11½	—	38	After 16 wk. on daily vitamin A intake of 2000 international units 1 nummular lesion on each hip, which became slightly larger in next few months; no generalized spreading during last 2 winters; weight varied from 110 to 115 pounds.
3	—	—	—	—	Weight gain from 10½ to 118 pounds on restricted diet; resumption of normal diet followed in 8 wk. by relapse.
4	—	—	—	—	No change in weight on diet; no further improvement observed on daily vitamin A intake of 1500 international units for 5 mo.
5	60 61	—	47 48	—	Slight relapse after 11 mo. on restricted diet, followed by continued spreading; diet discontinued on complaint of fatigue, anorexia and weight loss of 6 pounds.
	64 80 90	—	34 38 38	—	Daily intake of approximately 800 international units of vitamin A in 2nd phase.
6	—	—	—	—	Relapse 4 wk. after resumption of normal diet followed by continued spreading; another relapse with continued spreading 8 wk. after resumption of normal diet.
7	—	—	—	—	No improvement; patient unable to maintain normal caloric intake on restricted diet; weight loss of 9 pounds.
8	48 55 37	75 51	35 56 42	35 40	Weight gain of 7 pounds on restricted diet; relapse 6 wk. after supplementation of intake with carotene equivalent to 20,000 international units of vitamin A daily.
9	18 38	41	28 30	23	Relapse 6 wk. after change to diet restricted only in vitamin A intake; weight loss from 112 to 105.5 pounds.
10	<7 14	22 63	44 43	44 55	Relapse 3 wk. after resumption of normal diet because patient was unable to maintain a normal caloric intake and lost 5 pounds in weight.
11	21	—	48	—	No weight change on diet.

*Carotene intake unlimited. 3 tablespoons of mineral oil daily added to diet, since mineral oil has been shown to interfere partially with absorption of carotene from the gastrointestinal tract.²⁵

Of the 6 female patients 5 showed complete clearing, and 1 marked improvement, whereas of the 5 male patients 2 showed complete clearing, 1 marked improvement and 1 slight improvement and 1 remained unimproved. One patient (Case 5), whose lesions had completely subsided within twenty weeks, experienced a slight relapse after having been on the restricted diet for eleven months. He was unable to maintain a sufficient caloric intake, had lost 6 pounds and complained of tiredness and anorexia. These symptoms disappeared soon after the resumption of a normal unlimited diet, the psoriasis, however, continued to spread during the following ten months. Improvement was observed

continued this patient again showed marked improvement.

Plasma carotene and vitamin A determinations were not done in these cases prior to the beginning of the diets low in vitamin A. Determinations in 6 patients during the dietary regime, however, ranged from an undeterminable amount to 80 microgm of carotene and from 23 to 48 microgm of vitamin A per 100 cc of plasma. For comparison, the plasma values of 26 normal subjects on an unrestricted dietary regime showed an average of 149 microgm of carotene (range, 65 to 237 microgm) and an average of 43 microgm of vitamin A (range, 26 to 64 microgm) per 100 cc.

Corresponding values in 25 other psoriatic patients prior to dietary treatment were 139 microgm of carotene (range, 65 to 310 microgm) and 51 microgm of vitamin A (range, 28 to 73 microgm) per 100 cc of plasma. To date, plasma carotene and vitamin A levels have been determined at intervals of two weeks in 8 of these patients who have been on the restricted diet for a period up to ten weeks. The carotene levels showed a reduction of from 35 to 68 per cent of the original value within the first two or three weeks and continued to decrease, whereas plasma vitamin A values remained unchanged.

DISCUSSION

Wald et al.³⁵ showed that subjects saturated with vitamin A did not develop signs of vitamin A deficiency even after a period of about six months on a diet limited to 100 international units or less daily. Within slightly more than a week after the deficient diet had been begun, the plasma carotenoids dropped from normal to extremely low levels. The plasma vitamin A levels, however, maintained the initial maximal values throughout the entire deficiency. Our findings are in accordance with the results of these authors and similar observations reported by Brenner and Roberts.³⁶

The lack of noticeable changes in vitamin A plasma levels coincident with vitamin A restriction, however, does not exclude the possibility of a reduction of the vitamin in body stores that might be biologically effectual prior to a measurable decrease in plasma vitamin A levels. Lindqvist³⁷ observes that functional changes that are undetectable by available methods may occur before a decrease of the plasma vitamin A levels and other typical deficiency symptoms become apparent.

Furthermore, the possibility that the carotene itself had a direct influence on skin metabolism must be considered. It has been pointed out that the conversion of carotene to vitamin A probably occurs in other tissues besides the liver^{38, 39} and that the carotene may have biologic functions in addition to being the precursor and main source of vitamin A.³⁹⁻⁴¹

It should again be emphasized that the restricted diet used in this study included a normal amount of fat. This eliminates the possibility that a decrease of the cellular fat content of the epidermis thought to be achieved by the Grütz-Bürger low-fat diet is the specific mechanism responsible for the favorable reaction of psoriasis to the low vitamin A diet.

No definite statement, however, can be made regarding whether or not stimulation of keratinization due to vitamin A restriction is the basis for the observed improvement. Further investigation of these problems is necessary.

SUMMARY

Eleven patients with severe and persistent psoriasis vulgaris were maintained on a restricted diet

allowing 150 to 300 international units of vitamin A daily. Seven patients showed complete clearing of the lesions, 2 marked improvement, 1 slight improvement and 1 no improvement. Relapses occurred in 7 previously improved patients consequent to the resumption of a normal unrestricted diet or supplementation of the restricted diet with carotene.

The values of the plasma carotene and vitamin A levels determined in 6 cases while the patients were on the restricted diet are compared with those of 26 normal persons and 25 psoriatic patients on an unrestricted dietary regime.

The theoretical basis of this study and the related problems of carotene and vitamin A metabolism are discussed.

This dietary restriction is not considered a practical therapeutic regime. It affords an opportunity for further investigation of the metabolic aspects of psoriasis.

TIME OF ELECTION FOR ABDOMINAL SURGERY IN CHILDHOOD*

EDWARD J. DONOVAN, M D †

NEW YORK CITY

THE majority of abdominal surgical conditions in children under one year of age are due directly to some developmental anomaly. Infection, which plays a minor role in the abdominal surgery of the first year of life, subsequently forms the basis of many pathologic processes as it does in adult life. The processes found in infants are identical with those observed in adults, except that they are modified by conditions peculiar to early life. The modifying factors are often not entirely a disadvantage to the surgeon, for an infant's failure to co-operate makes the examiner observe more carefully and judge more keenly.

The process of growth and development has a definite effect on the course of many diseases in infancy and childhood. These factors frequently make disease sudden in its onset, short in its course and more intense in its manifestations. These same processes, however, often come to the aid of the surgeon, as they do in overcoming by growth the malalignment of a fracture or in the spontaneous healing of an incisional hernia.

It has been stated, and I believe quite without justification, that diagnoses are much more difficult to make in children than in adults. It is true that the surgeon must make his diagnosis not only without the co-operation of the child but also, at times, in spite of the child's efforts. I believe that if the examiner follows a definite pattern in his examination, seizing his opportunities as they present themselves and first of all gaining the child's confidence by not hurting him, the effort will be highly successful.

Anyone who considers an infant as a small edition of an adult will encounter many difficulties. Children tolerate the loss of fluid, particularly blood,

much worse than adults do. Gentle handling of the tissues, with careful hemostasis, is one of the first rules of abdominal surgery in childhood. Infants resist vigorously up to a certain point, but it should not be forgotten that there is a definite limit to the amount of surgery that a baby can tolerate. There is practically no indication for the exploratory laparotomy performed in adults, nor is there any abdominal condition so acute that the child need be operated on before he is properly hydrated. Many an excellent operation has been spoiled because the baby was dehydrated, anemic, exhausted and in no condition to stand the operation when it was performed, whereas a delay of perhaps an hour or two would have made success unquestionable.

This paper deals with the time of election for abdominal surgery of children. That there is a time of election for many operations goes without saying. The scope of such a title, however, makes it necessary for me to group many of the more frequent conditions since time does not permit a more detailed description of many of them.

The earliest emergency, which requires attention when the baby is but a few hours old, is hernia into the umbilical cord. The sac of the hernia, made up of amnion and peritoneum, is so thin, that, when it gets dry, it cracks and thereby permits infection to enter the peritoneal cavity from the outside. Many of these infants are operated on when they are less than twelve hours old. The umbilical vessels are ligated within the peritoneal cavity, the sac cut away, and the defect in the abdominal wall closed with through-and-through silk sutures.

A much more serious condition, making itself evident when the baby receives his first drink of fluids, is congenital atresia of the esophagus. In 85 per cent of cases the anomaly consists of an upper, closed esophageal pouch, completely separated from the lower pouch, that communicates with the trachea at or near the bifurcation. In the

*Presented at the New England Postgraduate Assembly Boston October 30 1946

†Associate professor of surgery Columbia University College of Physicians and Surgeons attending surgeon St. Luke's Hospital and Babies Hospital

presence of great distress when the baby is first fed, atresia of the esophagus should be suspected, the suspicion is confirmed if the passage of a catheter encounters a complete obstruction 12 to 15 cm from the anterior alveolar margin. Such infants should have an immediate operation. If the diagnosis is not made before the age of three or four days, aspiration pneumonia will have occurred when the surgeon is ready to operate, owing to the aspiration of secretions from the upper esophageal pouch. Although an exploration may be done with local anesthesia, every hour that is saved in making the diagnosis improves the chances of survival. The ideal operation is end-to-end anastomosis of the two esophageal segments. Unfortunately, this is not always possible to accomplish because of the shortness of the upper esophageal pouch. Anastomosis, if done with the slightest pressure on the suture line, almost always fails.

Pyloric stenosis occurs about seven times more frequently in boys than in girls and often in the first child of the family. The Fredet-Ramstedt operation is curative and should be done just as soon as the diagnosis has been made by palpation of the tumor and as soon as the baby is completely hydrated. The tumor must be felt in every case of pyloric stenosis. If such a criterion is not established, many infants are needlessly operated on for pyloric stenosis.

Congenital obstructions of the duodenum may be divided into two main groups, depending on whether the obstructive lesion is in the lumen of the duodenum (intrinsic) or due to some extraluminal condition (extrinsic). The extrinsic lesions are duodenal bands, volvulus and fixation of the duodenum in an abnormal position. These lesions usually start as incomplete obstructions and become complete perhaps while the baby is in the hospital for observation. The intrinsic lesions comprise diaphragm or membrane, atresia of the duodenum and stenosis of the lumen, and usually give symptoms of complete obstruction immediately after birth, requiring an extensive abdominal operation when the infant is but a few hours old. Success with this type of surgery depends on how quickly the diagnosis is made and on the thoroughness of preparation before operation.

The diagnosis of intestinal obstruction in the newborn may be made by the taking of a flat plate of the abdomen. The site of obstruction is often determined in this way from the configuration and distribution of gas shadows, but it is rarely possible to state exactly what the cause of obstruction is. Any patient with intestinal obstruction should be operated on without delay, for an hour or two frequently makes considerable difference in the success of the operation. I should like to emphasize the use of the plain film rather than to delay operation to take x-ray films using barium or some other medium. All the information necessary may be

obtained by a plain film. Mixtures, such as barium, are dangerous in a potential intestinal obstruction, since an incomplete obstruction may thereby be made complete. Lipiodol is often used instead of barium in the x-ray study of duodenal obstruction because there is no danger of its causing obstruction.

Idiopathic intussusception is one of the most frequent surgical emergencies in early life. About 90 per cent of cases occur in male infants between the ages of five and eighteen months. The history is typical in practically all cases and often helps in establishing the diagnosis. A typical history shows a sudden onset of acute abdominal pain in a healthy, vigorous male child. This is followed by the passage of blood and bloody mucus by rectum. The diagnosis is made by palpation of the typical sausage-shaped abdominal mass. It has been wisely stated that every hour over twelve hours that an intussusception remains unreduced decreases materially the surgeon's chances of reducing it. Again, the x-ray diagnosis of intussusception is not necessary and only apt to delay the operation.

Every patient with congenital obstruction of the bile ducts should be operated on as soon as the diagnosis has been made, in the hope that sufficient extrahepatic-duct system is present to make it possible by anastomosis to deliver the bile into the intestinal tract. Unfortunately, enough of the duct system is not present in many cases. Any part of the extrahepatic-duct system may be absent. If there is delay in operation the duct obstruction may cause an extensive cirrhosis of the liver, even though it has existed but a few weeks.

Great progress has been made in the past few years in the surgical treatment of congenital diaphragmatic hernia. This diagnosis may also be made by x-ray study of the chest. Every patient who has either small or large intestine in the chest is a potential candidate for intestinal obstruction — one of the worst complications that can happen in diaphragmatic hernia. These patients should be operated on as quickly as they can be prepared for operation. We have successfully operated on several young infants who were often in such respiratory distress that they were taken to the operating room in an oxygen tent. They were anesthetized, and an intratracheal catheter was inserted, and the operation was carried out without incident.

No discussion of this subject would be complete without mention of the care of inguinal and umbilical hernia and undescended testis — conditions that cause many serious problems in the first year of life. A great many umbilical hernias are found in infants with rickets, and many of them heal spontaneously without operation up to the age of four years. For this reason, operation is not performed — unless the hernia shows signs of incarceration — until the child is four years old. Few umbilical hernias heal spontaneously after that age. Similarly, many congenital inguinal hernias heal

spontaneously during the first year of life. The indication for operation in the first year of life, therefore, is that the hernia becomes incarcerated frequently. After the first year few inguinal hernias heal spontaneously, and the patients should be operated on. The results are excellent, since recurrence in a child is almost unheard of. In my experience many undescended testes do not descend to the scrotum because of a mechanical abnormality, and hormone injections are useless. All patients with undescended testes should be operated on before puberty, since the testicle undergoes its greatest development at that time, and there is much more chance of proper growth if the testicle is in the scrotum when puberty occurs. The ideal age for operation is between eight and twelve years. A Torek operation is done in all cases, since the results are far better than those obtained with other methods.

Acute appendicitis may occur at any age; several cases have occurred in infants under one year of age, and many cases have been observed in adults as old as eighty-eight and ninety years. The history in infants and children is exactly the same as that in adults; in practically all cases the onset occurs with epigastric pain that in about six hours localizes in the right lower quadrant and is followed by vomiting. The temperature is apt to be no higher than 101°F., and the white-cell count is almost always increased to 15,000 or 20,000, with a predominance of neutrophils. Abdominal examination almost always reveals general tenderness and muscular rigidity, but the most important of all abdominal signs is the definite local tenderness over McBurney's point, often accompanied by rebound tenderness. Operation should be done immediately; for delay converts a simple operation into a complicated one. The only point about the operation that I wish to stress is the use of the McBurney incision in all male children and in all female children up to the onset of the menses. After that time one must be more cautious in using the McBurney incision in girls, since many pelvic conditions simulate acute appendicitis and cannot be properly cared for through a McBurney incision. Nothing can overcome the difficulties caused by delay in diagnosis. A child with a ruptured appendix and general peritonitis in the hands of a master surgeon is not so well off as one whose appendix is removed before rupture, perhaps by a surgeon of much less skill. Although I do not like to operate on patients unnecessarily, I believe in giving the child suspected of having acute appendicitis the benefit of the doubt in every case.

Another group of conditions well worth considering is that associated with gross hemorrhage from the intestinal tract in infancy. The first to be mentioned in this category are intestinal polyps, which are often found singly in the rectum but

may be found in any part of the colon. Those in the rectum are almost always palpable on digital examination or at least may be easily found by proctoscopic examination. The diagnosis of polyps higher in the colon may be more difficult, but usually they can be seen on the x-ray film if double contrast mediums are used. Meckel's diverticulum is often the cause of an intussusception or other form of intestinal obstruction but frequently first makes its presence known when the child has a serious intestinal hemorrhage. Meckel's diverticulum often contains gastric mucous membrane that becomes ulcerated, causing serious hemorrhage. Unfortunately, x-ray examination is of no help in the diagnosis of Meckel's diverticulum, which must be made by the exclusion of other possibilities and by surgical exploration. It should not be forgotten that this condition is one of the most frequent causes of gross intestinal hemorrhage in childhood.

Another interesting member of this group is duplication of the small intestine, a potent cause of gross intestinal bleeding. Such duplications are also called enterogenous cysts and are the result of the development of embryonic rests. They are usually found in the terminal ileum at about the point where Meckel's diverticulum occurs, but differ from the diverticulum in that they are found in the mesentery of the intestine that they parallel, whereas Meckel's diverticulum is always found on the antimesenteric border of the intestine. The important thing to remember about duplications is that they are developed in the mesentery and have the same blood supply as the bowel that they parallel but frequently do not have the same type of mucous membrane. They often contain gastric mucous membrane and are the site of hard, indurated, chronic gastric ulcers. Because they have the same blood supply as the bowel, they cannot be removed without compromising the blood supply and therefore necessitate resection with the parallel intestine. Many duplications communicate with the bowel, but others do not. Again, they do not show on the x-ray film but must be seriously considered if the patient has had a gross intestinal hemorrhage.

Duodenal ulcers occur in children but not nearly so often as they do in adults. The diagnosis must never be forgotten, since the ulcer may well be the cause of severe hemorrhage, as in adult life.

* * *

I hope that I have made it clear that abdominal surgery in childhood differs considerably from that in adults and that infants and children are excellent patients for carefully planned and promptly executed abdominal operations. They respond most satisfactorily to gentle handling of their tissues and will recover in spite of the greatest odds if they are given a chance.

ALLERGIC MANIFESTATIONS AFTER THE INJECTION TREATMENT OF VARICOSE VEINS*

ELIZA A. MELKON, M.D.,† AND DOROTHY K. SCHEIDELL, M.D.‡

BOSTON

THE treatment of varicose veins by the injection method started in Europe, being used in 1904 by Tavel and in 1912 by Linser. During and after World War I numerous sclerosing agents were employed by Sicard and Gaugier, Montpellier, Genevrier and Dowthwaite, Noul and Troisier. Melkon¹ reviewed the history of the treatment of varicose veins in a paper published in 1929. Since then, various sclerosing agents have been used by many surgeons who gave injections freely and without too much consideration of possible dangers. It is time to call attention to the possible dangers in the use of sclerosing material.

The recent trend in the management of varicose veins is surgical, with high and multiple low ligations and divisions of the long and short saphenous veins and their branches or high and low ligation and stripping of the saphenous veins, and this has eliminated numerous injections; nevertheless, the use of sclerosing agents for postoperative cases, certain types of varicose veins and internal hemorrhoids is still frequent. Various sclerosing agents have been employed in this country, but we speak only of those formerly and at present in use at the New England Hospital for Women and Children and the Mount Auburn Hospital: a 20 to 25 per cent solution of sodium salicylate, an 18 to 25 per cent solution of sodium chloride, quinine hydrochloride and urethane, sodium morrhuate, and Sylnasol. A good sclerosing agent must be safe, effective and painless. Sodium salicylate and sodium chloride solutions, which were first used, were good sclerosing agents and were also safe; they caused cramps after the injection, however. Then, in succession, quinine hydrochloride and urethane, sodium morrhuate and Sylnasol, were employed.

There are numerous references in the medical literature to the allergic reaction of sclerosing reagents. In 1936 Lewis² reported anaphylaxis due to sodium morrhuate, and in 1937 Dale³ reported a reaction to the same drug. Subsequently, Holland,⁴ McCastor and McCastor⁵ and Praver and Becker⁶ described reactions to sodium morrhuate. In 1940 Kadin⁷ stated that these dangers could be eliminated by the routine skin testing of all patients prior to injection. But in 1941 Rosenzweig, Ascher and Zlatkin⁸ reported 938 cases, with reactions in 16 cases, of which 2 gave positive and the other 14 gave negative skin reactions.

The purpose of this paper is to report eight episodes (in 6 patients) of constitutional anaphylactic-like reactions that occurred following the injection of varicose veins with quinine hydrochloride and urethane, sodium morrhuate and Sylnasol. These cases occurred in the twenty years from 1926 to 1945, inclusive. During that time 3037 other patients were treated with no reactions. Most of these allergic reactions occurred in patients who had received injections of sclerosing solutions at intervals of several months. Two patients received quinine hydrochloride and urethane, 3 sodium morrhuate, and 3 Sylnasol. Although three different solutions were injected, the allergic reactions were similar.

The following are brief abstracts of these cases.

CASE 1. M. R., a 32-year-old nurse, was first seen on January 2, 1929, because of pain and cramps in the left leg. There was no history of allergy. Physical examination was negative except for medium-sized varicose veins on both legs. The blood pressure was 110/70.

At weekly intervals 1 to 1.5 cc of quinine hydrochloride and urethane was injected into the varicose veins, and at the end of the 6 weeks all the previously injected veins had been obliterated. There were no constitutional or local allergic manifestations. Four weeks later the patient received 1.5 cc of the same agent. Immediately after the injection she complained of feeling ill and warm. She rapidly went into collapse, the pulse became rapid and weak, the respirations were shallow, and the blood pressure was 40/0. The eyes became congested and puffy, and the pupils were dilated. An urticarial rash appeared on the face and neck and then on the entire body. She complained of severe headache and numbness of the nose and lips as well as belching, nausea and vomiting. She was extremely weak but did not lose consciousness. A subcutaneous injection of 0.5 cc of a 1:1000 solution of adrenalin was given immediately, and the dose was repeated in 30 minutes. Also, 4 cc of spirits of ammonia in water was given by mouth, and cold wet compresses were applied to the forehead. The attack lasted about 1 hour, the pulse, blood pressure and respirations gradually returned to normal. The urticaria began to disappear, and the headache, nausea and vomiting ceased. After resting for 3 hours the patient was allowed to go home. On the next day the patient telephoned that she was slightly weak but otherwise had no symptoms.

Approximately 9 years after the allergic episode, bilateral high ligation and division of the long saphenous vein were done to relieve pain and heaviness of the legs. No further injections were given.

The patient was seen again 7 years later, when examination disclosed a few medium-sized varicose veins above the left external malleolus. On the assumption that she was allergic to quinine hydrochloride and urethane but would be able to take Sylnasol, 0.5 cc of the latter drug was injected after negative scratch and intradermal tests. The scratch test consisted of incision of the skin with a cutting-edge needle just deeply enough to penetrate to the dermis. A drop of full-strength Sylnasol was placed over the area and gently rubbed in, and the area was observed for 15 minutes. Then, 0.1 cc of a 1:10 dilution of Sylnasol was injected intradermally, and the area was likewise observed for 15 minutes. One hour after the first injection a second injection of 0.5 cc of Sylnasol was given. The patient returned in 1 week and received 1 cc of Sylnasol with no reaction. A week later 1 cc of Sylnasol was again injected. Immediately after the injection she had an attack of allergy similar to the

*From the New England Hospital for Women and Children.

†Chief of vascular diseases of lower extremities, New England Hospital for Women and Children; chief of vein clinic and junior surgeon of vascular diseases, Mount Auburn Hospital.

‡Assistant surgeon, New England Hospital for Women and Children.

reaction, 15 years previously, to the quinine hydrochloride and urethane injections

CASE 2. J K., a 40-year-old housewife, was seen on June 14, 1937, because of an ulcer above the internal malleolus of the left leg and marked varicosities on both lower extremities. There was no history of allergy. Physical examination was negative except for the ulcer and the varicose veins. The blood pressure was 118/80.

The patient was advised to have bilateral high and low ligations and divisions of the saphenous veins, but she refused and wished to have the varicose veins injected while she was receiving treatment for the ulcer once a week. At the first visit 1 cc. of quinine hydrochloride and urethane was injected, at the second visit 2 cc., and at the third visit 2 cc. At the fourth visit the previously injected varicose veins were obliterated, and the ulcer was almost healed. A few minutes after the injection of 2 cc. of quinine hydrochloride and urethane the patient began to feel warm and weak. The face and neck became red. Shortly thereafter there was a generalized urticarial rash, the pulse was rapid, the blood pressure fell to 60/0, the respirations were shallow, the eyes were congested and the lids puffy, and the pupils were dilated. Immediately, 0.5 cc. of 1:1000 solution of adrenalin was injected subcutaneously. One teaspoonful of spirits of ammonia in water was given by mouth, and cold wet compresses were applied to the head. The injected leg was lowered, and a tourniquet applied to the thigh for 10 minutes. The attack lasted 30 or 40 minutes. Gradually, the rash began to fade, the pulse, blood pressure and respirations became normal. The patient was allowed to go home after resting for 2 hours. She had no constitutional or local effects on the following day. Three months later bilateral high ligations and divisions of the long saphenous veins were performed. No further injections were given.

CASE 3. W S., a 60-year-old housewife, was admitted to the clinic on August 2, 1940, because of an ulcer on the right leg and varicose veins on both legs. The varicose veins were injected with 10 to 15 cc. of quinine hydrochloride and urethane solution. This was repeated five times at weekly intervals. The patient showed no allergic manifestations.

On March 25, 1945, the patient returned to the clinic. At that visit and again on April 12, April 26 and May 3 she received injections of 10 to 25 cc. of sodium morrhuate. There were no reactions to these injections. Two weeks later, however, a few minutes after the patient had been given an injection of 2 cc. of sodium morrhuate she stated that she felt warm and weak. There were blotches of urticarial rash covering the entire body, the pulse became weak and rapid, and the blood pressure fell to 60/0. Immediately, 1 cc. of a 1:1000 solution of adrenalin was injected subcutaneously. The injected leg was lowered, and a tourniquet was applied at the thigh for 10 minutes. The attack lasted for 30 minutes, after which the pulse and blood pressure gradually returned to normal. The skin rash began to fade, and after resting for 1 hour the patient was allowed to return home by automobile. On the next day she reported that she felt weak and had some pruritus.

CASE 4. J W., a 29-year-old housewife, was seen in the clinic on December 3, 1937, because of cramps in the legs. There was no history of allergy. Physical examination revealed a normal pregnancy of 7½ months' duration and tortuous varicose veins on both legs. The blood pressure was 110/70. Because of the pregnancy she did not receive an injection and elastic stockings were prescribed.

On April 22, 1938, the patient returned to the clinic and a series of four injections of sodium morrhuate were given at weekly intervals. She did not return to the clinic again until January, 1940, when she was given 15 cc. of sodium morrhuate, followed by injections of 15 to 25 cc. of the same drug every 1 to 3 weeks until November 22. At that time, her seventeenth visit since January, 25 cc. of sodium morrhuate was injected in two doses about 2 minutes apart. Immediately following the second injection she complained of pains in the legs, dizziness, weakness and a warm sensation. The pulse was weak and rapid. In about 15 minutes a marked urticaria all over the body and edema of the eyelids and face developed. The patient was given 0.5 cc. of a 1:1000 solution of adrenalin solution, and 15 minutes later received 1 cc. of the same medication. The attack lasted for

1 hour, at the end of that time the urticaria and edema had disappeared.

In 1942 this patient received four injections of sodium morrhuate without a reaction.

On November 5, 1945, the patient again returned to the clinic and was given 1 cc. of Sylnasol. On November 12 she received 2 cc. of Sylnasol, about 2 minutes after the injection she complained of feeling warm, faint and weak. The pulse was rapid and weak, the blood pressure was 80/0. Fifteen minutes after the injection a fine urticarial rash developed on the hands and arms. The patient was given 1 cc. of a 1:1000 solution of adrenalin, followed by 1 cc. of Coramine. The attack subsided in 1 hour. No injections have been given since this reaction.

CASE 5. D L., a 38-year-old housewife, was seen in the clinic on July 30, 1937, complaining of pain in both legs. There was no history of allergy. Physical examination revealed many large varicosities of the entire lower extremities. The blood pressure was 114/70. Bilateral high saphenous-vein ligations were done. During the year the patient received thirteen injections of sodium morrhuate. Seven injections were given in 1938, and three injections in 1941, each consisting of 20 to 35 cc. In 1942 she had eight injections. None of these injections caused any reaction. Three weeks after the dose on June 19, 1942, a ninth injection of 2 cc. of sodium morrhuate was given in two doses. Immediately afterward the patient felt hot and weak, and an urticarial rash developed all over the body. The pulse was barely perceptible, and the blood pressure was 80/40. She was given 1 cc. of a 1:1000 solution of adrenalin. In 1 hour the reaction had largely subsided.

CASE 6. V D., a 36-year-old housewife, was seen on December 7, 1944, because of pain and cramps in the right leg for the previous 5 years. The past history was negative for allergic diseases. She had observed a tendency toward fainting and dizziness on several occasions. She had had phlebitis of the right leg after delivery of a child 7 years previously. Physical examination disclosed a well developed and obese patient. The chest and abdomen were normal. The blood pressure was 110/60. Both legs were covered with large sacular and tortuous varicose veins.

On March 3, 1945, bilateral high and multiple low ligations and divisions of the saphenous veins were done. Two weeks later after a negative skin test, four injections of 1 to 2 cc. of Sylnasol were given at weekly intervals. Most of the varicose veins were obliterated, and the leg pain and cramps disappeared. There were no constitutional or local reactions. On November 30, 1945, when the patient returned for a follow-up examination, there were a few small varicose veins on the anterior aspect of the right leg. Injections of 15 cc. of Sylnasol were given in two places. One week later 2 cc. of Sylnasol were injected in three places. A few minutes after the injection the patient felt warm, weak and dizzy. A red rash appeared over the entire body. The pulse became weak and rapid and was hardly perceptible. There was moderate dyspnea. The blood pressure was 40/0. The eyes became congested, and the lids puffy. The patient complained of a severe headache and had nausea and vomiting. A subcutaneous injection of 0.5 cc. of a 1:1000 solution of adrenalin was given, and this dose was repeated in 20 minutes. A tourniquet was applied to the thigh for 10 minutes, and 1 cc. of Coramine was injected subcutaneously. The attack lasted for 1 hour, and then all subjective and objective symptoms gradually disappeared. After resting for 4 hours the patient was allowed to go home by automobile. On the next day she was up and around, but still rather weak.

* * *

In this series of cases the constitutional and allergic reactions occurred with dramatic suddenness. None of the patients had had a history of allergic manifestations, such as asthma, hay fever and urticaria. Two patients gave four negative skin tests, in the other 4 the skin tests were not done. Most of the patients had received injections of sclerosing solutions at preceding intervals of a few

months or more. Most of the severe reactions occurred after a temporary cessation of treatment, and in all cases the allergic manifestations appeared within one to five minutes after an injection. The patients had urticarial rash and were warm and weak, with rapid pulse, low blood pressure and puffy congested eyes, and in 2, nausea and vomiting occurred. None of the patients lost consciousness. The patients with the lowest blood pressures appeared to have the severest reactions. Two patients had allergic shock from quinine hydrochloride and urethane, 3 from sodium morrhuate, and 3 from Sylnasol. The symptoms were the same regardless of the drug used.

There are many theories concerning the phenomena of anaphylaxis and allergy. Of these, one has been advanced by Sir Thomas Lewis,⁹ who assumed that the union of antigen and antibody in the tissues caused an irritation in or on the cells of the tissues, with the resulting liberation of a histamine-like substance that produced the physiologic effect characteristic of anaphylaxis or allergy. Zimmerman¹⁰ believed that sclerosing solutions may mix with the liver protein and produce allergic reactions. A theory has been advanced that hemolysis occurs, contact of the susceptible patient's blood with the solution resulting in liberation of a protein substance that causes the reaction. K. M. Lewis² suggests that sodium morrhuate acts as a hapten and sensitizes susceptible persons, particularly if they have received an injection one or two weeks previously. Crip¹¹ states that a patient may become hypersensitive to the drug if more than seven or ten days elapse between injections. Drug allergy is not identical with protein allergy, since the development of sensitivity appears to be dependent on the combination of the drug with a body protein. The

exciting agent in true anaphylaxis is always a soluble protein. In acquired allergy, this is not necessarily so, for many nonprotein substances, such as drugs, are capable of acting as allergens.

It seems probable that the substance released from the union of antigen and antibody in the cells of the tissue is a histamine-like substance that either acts directly as a vasodilator on the smooth muscles of the small vessels or depresses the vasoconstrictor sympathetic nerves, thus increasing the permeability of the arterioles and producing a generalized skin rash and a low blood pressure.

SUMMARY

Eight attacks of allergic manifestations in 6 patients following the injection treatment of varicose veins are reported, and the possible explanations for these reactions are briefly discussed.

MEDICAL PROGRESS

RUBELLA (GERMAN MEASLES)*

CONRAD WESSELHOEFT, M D †

BOSTON

AT THE annual meeting of the Ophthalmological Society of Australia in 1941 Gregg¹ reported a series of congenital cataracts in 78 cases following attacks of rubella in the early months of pregnancy. Since then, numerous studies have been made regarding the prenatal influence of this disease with results indicating that the fetus may suffer a variety of defects leading to serious congenital malformations or that the fetus may be destroyed in utero with consequent miscarriage or stillbirth. Thus it is that a disease hitherto considered to be of little consequence and to require only differentiation from other exanthems has become a serious problem in obstetrics, medicine and public health. It is the purpose of this review to look backward through the history of rubella, to sum up the present knowledge of its pathogenesis, and to consider the numerous problems with which we are now confronted.

TERMINOLOGY

According to Emminghaus² rubella was first described by two German physicians, de Bergen in 1752 and Orlov in 1758. There followed numerous others who called attention to its manifestations under various terms but eventually under the title of *Roetheln*. This term was used both in England and in America, and it is under this heading in the first series of the *Index Catalogue of the Library of the Surgeon General's Office*. Owing to the early interest displayed by German writers and the acceptance of the term *Roetheln*, this disease came to be known as "German measles." In 1866 Henry Veale³ introduced the term "rubella," which is now accepted in English-speaking countries, and one to be encouraged for the simple reason that this disease is not a German form of measles or any other form of measles, but rather a distinct entity unto itself.

The terminology of rubella in different countries has been and still is a cause of confusion. The trouble lies in the historical background. The early German writers considered it to be a modified form of either measles or scarlet fever. Schönlein⁴ regarded it as a hybrid of both and gave it the name "rubeola" to distinguish it from "morbilli" or true measles. Eventually, rubeola came to be used to designate measles, but to this day *Rubeola* is used in Sweden and *rubéola* in Spain for rubella. In

France the term is modified to *rubéole*, and even in Austria *Rubeolae* is sometimes used in place of *Roetheln*. Consequently, in investigation of the literature, or in conversation with foreigners, it is necessary to keep these synonyms in mind.

While German authors wrangled over the relation of rubella to measles and scarlet fever, Willan,⁵ in England, described the condition as *rubeola sine catarrho* and remarked that "persons receiving the miasm in this form are peculiarly liable to a second attack of measles." In the next year, 1814, Maton⁶ in a paper read before the Royal College of Physicians described rubella as a disease entity. In 1840 Paterson,⁷ "unaware of any description of this disease in our language," entered into a historical review and proceeded to confuse it with scarlet fever and measles, citing among his cases a number of fatal ones. In 1940 an editorial in the *Edinburgh Medical Journal*⁸ entitled "One Hundred Years Ago" took Paterson's remark at its face value to the neglect of Maton's excellent observations.

John Homans,⁹ a president of the Massachusetts Medical Society, is credited with being the first physician in America to describe rubella. This he did in an unpublished paper before the Boston Society for Medical Improvement on April 14, 1845. Cotting,¹⁰ who was present at this meeting, presented a paper on the same subject in 1853 before the Norfolk District Medical Society. This was incorporated in a subsequent address delivered twenty years later, constituting the earliest published account of the disease in the United States. At that time an active interest in the disease had sprung up in this country, headed by J. Lewis Smith,¹¹ who contributed to the symposium on rubella at the International Medical Congress in London in 1881 — the only occasion on which this disease ever received so much attention. The interest culminated in the two classic works by Atkinson¹² and Griffith¹³ in 1887, and that of Corlett¹⁴ in 1902. A characteristic article of this period was written by Townsend¹⁵ in 1904. This author withdrew his previously expressed skepticism of the identity of rubella and described an epidemic in Boston, with a description of his cases. A comprehensive account was given by Schamberg and Kolmer¹⁶ in 1928. Throughout this era attention was given to establishing the entity of rubella, its symptomatology and course, and its differentiating characteristics. Nowhere in the literature prior to

1941 have I been able to find any trace of evidence that rubella in the course of pregnancy is a source of danger to the fetus. The latest extensive paper covering rubella appears in Christian's *Oxford Medicine*.¹⁷

ETIOLOGY

The causative agent of rubella is a filterable virus. In 1938 Steinmaurer¹⁸ claimed to have demonstrated the virus with the fluorescent microscope and to have isolated it on the chorioallantois of the egg embryo, but the evidence presented is by no means convincing. Hiro and Tasaka¹⁹ collected physiologic saline washings of the nasopharynx during the eruptive stage. The filtrate was injected subcutaneously into a group of 16 nonimmune children convalescing from chronic disease, of whom 4 exhibited a characteristic rubella rash, and 2 showed typical lymphadenopathy without any skin eruption. The incubation period was seven days in 3 cases, and eight, eleven and seventeen days in the others. Habel²⁰ used similar nasal washings obtained within twelve to twenty-four hours after the appearance of the rash. The filtrate was introduced by the intranasal, subcutaneous, intraperitoneal and intravenous routes into *Macaca mulatta* monkeys. Washings obtained from patients on the third day of the disease yielded negative results, whereas those obtained on the first day gave equally positive results from all four routes, although the monkeys did not always exhibit a rash. Habel also reported successful cultures on the chorioallantoic membrane of the chick embryo, although no specific pathologic lesions were found.

DISTRIBUTION

Rubella is widely distributed, being found in North and South America, Europe, Africa, Asia, Japan and Australia. Unlike measles it does not appear to be unusually severe when it first strikes on virgin soil.

AGE

Rubella, like measles, is rare in the first six months of life. Corlett¹⁴ remarks that "infants have contracted the disease a few days after birth." Measles is usually mild when it occurs at that time, and therefore rubella, if proportionately mild, might easily be missed. I have collected reports of 5 mild cases in infants ranging from eighteen days to two months old.¹⁷ After six months of age rubella takes its usual course, which being milder than measles and of shorter duration is frequently not reported. In fact, a physician may not even be called. In children's institutions the disease spreads freely. Thus, Michael²¹ reported 80 cases among 199 children, of whom all those under six years of age contracted the disease. Humphrey and Ekermeyer²² found that 48 per cent of the children exposed were attacked, whereas Geiger²³ observed

an attack rate of 12 per cent among school children. Thus, it appears that in children's institutions rubella exhibits a fairly high attack rate, whereas among day-school children the rate as reported is low. To a certain extent this can be explained as failure in reporting the day-school cases. On the other hand, the rather high incidence of rubella among young adults in colleges and in military life suggests the possibility that more children escape rubella than they do measles. Contagious hospitals usually have more cases of rubella among young adults than among children. This is due to the fact that rubella is not generally hospitalized except when the cases arise in dormitories or barracks. The disease rarely attacks those over forty years of age. Simpson,²⁴ however, has recently reported a case in an epidemic at Dorset, England, in which the patient was eighty-two years old.

INCUBATION PERIOD

Maton,⁶ Emminghaus,² Thomas,²⁵ Earle²⁶ and Pospischil²⁷ all arrived at the approximate figure of eighteen days for the incubation period. Many authors have been content to compile figures given by previous writers along with the addition of their own observations, until 41 series are listed by Schamberg and Kolmer¹⁶ without references and without any discrimination regarding possible faulty diagnoses easily detected in the original sources. As such, these compilations are not only worthless but also misleading. From a single three-hour exposure to the onset of the eruption exactly eighteen days elapsed in a case reported by Lindberg.²⁸ This figure is confirmed by a chart presented by Aycock and Ingalls²⁹ of an epidemic at a boys' boarding school.

PERIOD OF INFECTIVITY

Since it is now apparent that the virus of some of the acute exanthems resides in the upper respiratory tract during the prodromal period and the height of the eruptive stage, their spread occurs during the prodromal period before a diagnosis has been established and isolation carried out. In measles the predominant catarrhal symptoms with sneezing and coughing cause the air about the patient to be filled with virus-laden droplets. Chicken pox, without such catarrhal symptoms, however, is spread presumably from the upper respiratory tract prior to the eruption.^{30, 31}

Isolation of the virus of rubella from the upper respiratory tract during the first forty-eight hours of the eruption^{19, 20} lends support to the contention that rubella is spread from the upper respiratory tract. Griffith¹³ observed that 63 of his patients in children's institutions contracted the disease in spite of prompt and careful isolation of all cases with the appearance of the rash. Consequently, the period of infectivity appears to precede the eruptive phase. Furthermore, it is highly probable that

with the fading of the rash the period of infectivity terminates as in measles. This is supported by Habel's²⁰ negative results from nasal washings taken on the third day of the disease and his demonstrations of the virus in the blood of patients bled within twelve, twenty-four and thirty hours of the onset of the rash, but not in blood taken on the third day. Since the rash is often of relatively short duration, isolation precautions established after the appearance of the rash are merely attempts to control the spread during the last part of the period of infectivity. In the light of the available evidence, Geiger's²¹ recommendation that cases be isolated for the duration of palpable lymph nodes is hardly tenable, particularly since the postauricular nodes may remain swollen for an indefinite period. Consequently, isolation beyond the period of the eruption is of doubtful value.

IMMUNITY

A lifelong immunity to rubella is usually established by an attack. Late second attacks have been recorded, however.²² Just how this permanent immunity is established and in what manner it is lost is one of the great problems of virology²³ and cannot be entered into here. Relapses occur and are not to be confused with late second attacks, which are rare. Griffith¹⁸ reported a relapse in 3 cases, once on the eleventh day and twice in the third week. Humphrey and Ekermeier²² observed relapses in 19 of 305 cases (6.2 per cent). The relapse, which was usually milder than the original attack, occurred in the third week in 15 cases, in the fourth week in 3, and on the forty-first day after the original attack in 1. These authors are of the opinion that the establishment of immunity is often delayed, allowing reinfection through subsequent exposure during this period of partial immunity. A number of factors may enter into the mechanism of this phenomenon, which I have observed on rare occasions at the Haynes Memorial. Probably the reason I have seen this so rarely is that the patients admitted with rubella during my term of service were discharged before a relapse could take place. On the other hand, when rubella had broken out on a scarlet-fever ward, the patient was sometimes detained because of scarlet-fever complications long enough to suffer a relapse from rubella. In such cases the relapse was identical in severity with the first attack.

COURSE

Rubella is generally considered to be the mildest of the exanthems. For the most part the patient complains of no discomfort throughout the course of the disease.

In children under observation in a hospital ward a slight rise in the temperature during the twenty-four hours preceding the eruption may be the only prodromal sign. In adults the prodromal symptoms

are in proportion to the severity of the subsequent eruption. In the severer cases among adults prodromal fever, headache, muscular aches and pains and the characteristic enlargement of the lymph nodes have been encountered. Anorexia, nausea and vomiting are rare.

The blood picture in the prodromal stage is of peculiar interest. A marked leukopenia is sometimes observed, both in children and in young adults, but this phenomenon is by no means constant. On two occasions, however, we have correctly suspected the diagnosis prior to the eruption through known exposure and white-cell counts of about 2000. In the eruptive stage this leukopenia is apt to shift to a lymphocytosis, along with the appearance of a few monocytes. Careful blood studies by Lindberg²⁴ failed to yield any blood findings of diagnostic value because of the wide variability. Hynes²⁵ carried out serial white-cell counts on 61 adult patients; these generally showed an absolute leukopenia at the onset, changing to an absolute lymphocytosis on the sixth day and a neutrophilic leukocytosis after ten days. These findings offered no difference from those observed in measles. During the first week an increased sedimentation rate was observed in a quarter of his cases.

At the Haynes Memorial Hospital 1046 patients have been admitted for rubella. Only 5 of these were admitted prior to the beginning of my term of service, and I was one of them — rubella being the only disease that I have acquired from my work at this hospital. Besides these admissions there have been a number of outbreaks of rubella in the convalescent scarlet-fever wards. None of these patients suffered any serious complications, with the exception of 2 who were admitted with rubella encephalitis and 1 mild case of encephalitis that developed six days after the onset. One patient in the third month of pregnancy miscarried spontaneously on the sixth hospital day. The bulk of the adults were college students, patients referred from the armed forces, student nurses and interns from our own and other hospitals.

The exanthem may be ushered in by a brilliant generalized erythema of the face, as noted by Pospischill.²⁷ This lasts for only twelve to twenty-four hours and precedes the severer types of rash. More frequently, the eruptive stage begins with the appearance of small, pale, rose-pink macules that come out first on the face and scalp and spread downward over the trunk and extremities. In the severer cases the macules may coalesce in certain areas, especially over the lower back and buttocks. Only in severe cases are macules found in the axillas, the popliteal spaces, the palms and the plantar surfaces. The severer the eruption, the longer it remains, and in the severe type a coppery tint may appear as in scarlet fever. Such cases may be accompanied by considerable fever and may be followed by a furfuraceous desquamation of the face

and trunk as the rash subsides Schamberg and Kolmer¹⁶ describe an unusual case in a twenty-seven-year-old nurse with severe prodromal symptoms of fever, chilliness, headache, vomiting and cervical lymphadenopathy that lasted for five days. The macules first appeared below the knees and spread upward, with many crescent formations. Vomiting and fever persisted. The face was finally involved on the third day, and the rash disappeared on the sixth day. The incubation period had been only thirteen days. This case reminds one of the severest type of smallpox, *variola purpurica*, in which the incubation period is greatly shortened.

In general the macules remain discrete. There are, however, several outstanding characteristics of the disease.

The eruption comes out suddenly on the face, from which it tends to fade rather abruptly in the milder cases, so that on the second day the rash begins to fade from the face, although it is then well marked over the trunk.

The eruption tends to be kaleidoscopic or, as some authors put it, polymorphous. The first term is more appropriate, since the eruption may be macular at first and may then assume a more punctate appearance. Thus, the rash may resemble measles on one day and scarlet fever on the next. The fading of the rash from the face on the second day may suggest scarlet fever, which only rarely involves the face.

Catarrhal symptoms are absent unless due to a secondary infection, such as the common cold.

Conjunctivitis is not constant, but when present is characteristic in that the orbital conjunctivas are involved, giving a suffused pink to the whites of the eyes. This is in marked contrast to the definite palpebral conjunctivitis seen in measles. Photophobia is extremely rare, lachrymation is absent, and there is none of the purulent sticky discharge frequently seen in measles.

Lymphadenitis is particularly characteristic over the mastoid region. These postauricular lymph nodes may be so enlarged as to be not only palpable but also visible from a distance. Klaatsch³⁴ mentions that on this symptom alone the diagnosis of rubella may be ventured in the dark. In such cases a child may complain of "earache" without any evidence of otitis media, whereas in other cases with similar enlargement of the lymph nodes there is neither pain nor tenderness. The postauricular nodes, however, are not always affected, and the absence of enlargement need not preclude the diagnosis of rubella. Moderately enlarged suboccipital and posterior cervical chains of lymph nodes are frequently palpable, as in measles. Furthermore, there may be generalized prominence of the lymph nodes in the axillas and groins. The

enlargement of the postauricular nodes may persist for weeks and even for years.

Fever is sometimes entirely absent. Often, a slight fever extends from the prodromal period through the height of the eruption. In the severe cases there may be chilliness and a temperature as high as 104°F, but for the most part such patients are rarely as uncomfortable as those with proportionately severe measles or scarlet fever.

Forchheimer,³⁵ of Cincinnati, is responsible for much of the confusion that exists regarding the appearance of the throat in rubella. In 1898 he described the enanthem as small "rose red spots" on the soft palate and uvula that fade away within twenty-four hours, "sometimes leaving a yellowish brown pigmentation." In another article he³⁶ refers to the enanthem as "small, discrete, dark red, but not dusky papules which disappear in a short time, leaving no trace behind." These diverse descriptions were advanced at the time when Koplik had given his classic account of the throat lesions in measles, which have come to be known throughout the world as "Koplik spots." Consequently, writers on rubella began to refer to "Forchheimer spots." Authors are apt to spell the name incorrectly when they depict the spots according to one or the other of Forchheimer's versions. At times, an author remarks that he has also observed something quite different, whereupon he describes the other condition, entirely ignorant of Forchheimer's other version. The fault seems to lie with Forchheimer, who failed to clarify his position. The fact is that the enanthem if present is fleeting, and is sometimes kaleidoscopic in character like the exanthem. I have had occasion to demonstrate to students both versions as well as perfectly normal looking throats in the course of rubella. Humphrey and Ekermeier²² failed to find an enanthem in any of their 305 cases. In my opinion there is nothing pathognomonic about the appearance of the throat in rubella. Bennett and Copeman³⁷ reported pharyngitis, follicular tonsillitis, congestion of the nose "without catarrh" and soreness of the gums in a severe epidemic in the British Expeditionary Forces. Todd³⁸ also noted the same soreness of the gums in her own case, "as though her teeth were falling out."

The appearance of the tongue also lacks any diagnostic significance. At times the bright strawberry tip may be observed, but the subsequent prominence of the papillae over the entire surface—frequent in scarlet fever—is never present. Pospischil³⁷ and Lindberg²⁸ have remarked on the difficulty sometimes presented in differentiation of the tongue of rubella from that of scarlet fever. I can share this view only so far as to say that the tongue early in mild scarlet fever, as in rubella, often appears to be perfectly normal.

The spleen is sometimes palpable just as it is in some of the other common virus diseases, such as mumps and measles

UNUSUAL FORMS

Rubella ecchymotica has been described by Ström,³⁹ of Stockholm. This author discusses 2 cases in adults in which the enanthem and exanthem were distinctly ecchymotic in character. Aside from these ecchymoses there was no loss of blood. The patients were not acutely ill, and the blood findings were normal. This type of eruption, which I had occasion to observe in some of the sailors referred from the Coast Guard, as well as in several college students, is due to a lowered capillary resistance. The character of inflammation in the acute exanthem is dependent on the nature of the toxic material present, and it is only by the outward manifestations that the diagnosis of the various exanthems of virus origin can be made. Landis⁴⁰ states that the permeability of the capillary endothelium is increased in all types of inflammation. The degree of inflammation brought about is further dependent on the amount of virus present and the spreading factor, both of which influence the resistance offered by the capillary epithelium. In rubella the exhibition of an ecchymotic character in the eruption implies a soil in the skin and mucous membranes that allows greater inflammation with greater permeability of the capillary endothelium but without necessarily augmenting the constitutional toxicity, provided other organs are not involved. These ecchymoses are responsible for the coppery hue that accompanies the fading of a severe eruption alluded to above.

Modified rubella, like modified measles, implies a minimal attack in which the eruption is barely visible or never seen. The diagnosis is established in these cases by the characteristic lymphadenopathy with or without fever, by the circumstantial evidence of exposure with an appropriate incubation period and sometimes by the added confirmation of transmission of the infection to other persons. Lindberg²⁸ reported such a case without a rash in which the postauricular lymph nodes were markedly prominent. Flöystrup⁴¹ reports the case of his own son, who, after a definite exposure in school, exhibited characteristic lymphadenitis, conjunctivitis, vomiting and slight fever, with only a few pale macules on the cheeks lasting but a few hours. The boy's younger brother, however, contracted a typical attack of rubella from this exposure. The title used by Flöystrup, "rubella without a rash," is misleading, and the case has been used as an example of rubella without a rash, which it is not. Habel²⁰ reports 2 cases of rubella without a rash, 1 of which is misleading. We have seen measles modified in newborn infants and by the late administration of convalescent serum or gamma globulin when the eruption was exceedingly slight and fleeting. There-

fore, although rubella may be modified through high resistance to a point where no rash occurs, it is also possible for a rubella rash to be so fleeting as to escape the observation of the attending physician — just as authors in quoting Flöystrup's case have failed to note that an eruption did take place.

DIFFERENTIAL DIAGNOSIS

The greatest difficulty in the diagnosis of rubella has occurred in the differentiation of this disease in its mildest form from modified measles after the late administration of convalescent serum or gamma globulin. One must lean heavily on the circumstantial evidence of exposure, because the usual catarrhal symptoms of measles, as well as Koplik spots, may be absent. Measles with Koplik spots should never present any difficulty.

A mild scarlet fever can make trouble, especially if the patient with rubella is seen on the second or third day when the rash has disappeared from the face and is punctiform. Scarlet fever does not give a rash on the face, except on the forehead and temples. When it does so the eruption is rough and feels like coarse sandpaper over the forehead, and usually is accompanied by a severe rash over the trunk with all the earmarks of scarlet fever. In rubella the throat may be inflamed from heavy smoking or from some secondary infection. At the onset of mild scarlet fever there may be no lymphadenitis, or if present it will be manifested in the anterior cervical chain in contrast to rubella, which involves the postcervical chain and the suboccipital and postauricular lymph nodes. As pointed out above, the tongue at the onset of scarlet fever may not have taken on the characteristic enlargement of the papillae. The kaleidoscopic character of the rubella rash is always helpful. A mild scarlet fever does not always desquamate, but the characteristic late peeling under the fingernails means that the patient has had scarlet fever, no matter how much the disease appeared to be rubella.

In the course of infectious mononucleosis a scattered, pinkish, macular eruption may come out over the trunk and extremities but, unlike rubella, is rarely marked on the face. The fever is apt to be much more prolonged. In the first few days the blood picture in infectious mononucleosis may not differ from that at the onset of rubella, but monocytes will appear in increasing numbers. Moreover, there may be a severe faucial angina with white fibrin deposit. Positive heterophil agglutination tests later on will confirm the diagnosis. A case of complete temporary heart block has been recorded as coming on in rubella, but the case as described might have been infectious mononucleosis.⁴²

Erythema infectiosum is most frequently found in Central Europe and is rare in England and America. The incubation period is from five to ten days.⁴³ The eruption appears first on the face, especially on the cheeks, as a papuloerythema, and

then on the extensor surfaces of the extremities, reaching the trunk last of all. The lesions are polymorphous, sometimes morbilliform or scarlatiniform in appearance and, according to Rolleston and Ronaldson,⁴⁸ often tend to be annular or gyrate. There is little or no fever and no lymphadenopathy. Eosinophilia is usually present, and the eruption persists for ten days.

Roseola infantum (exanthem subitum) is not to be confused with rubella. This disease occurs in infants, is attended with a high fever lasting three or four days and is often associated with convulsions. The laboratory findings are essentially normal. Slight generalized lymphadenopathy may be present, but the postauricular lymph nodes are not enlarged. The disease terminates with an abrupt drop of the temperature to normal and the appearance of a rubella-like eruption that promptly fades. The rickettsial diseases, such as typhus and Rocky Mountain spotted fever, may exhibit macular eruptions not unlike those of rubella. Even though no hemorrhagic lesions occur the constitutional symptoms are severe and persistent.

Late serum rashes associated with generalized lymphadenopathy are sometimes confused with rubella. But wheals are apt to develop, as in a generalized nettle rash. Drug eruptions, particularly from the sulfonamides, barbitol derivatives and quinine, lack the kaleidoscopic course of rubella. As in the conditions mentioned above, circumstantial evidence is of great importance. Erythema multiforme is differentiated by the prominence of the early eruption on the extremities and the circinate character of the lesions. The irregular form of rubella described by Schamberg and Kolmer¹⁶ and cited above under the discussion of the rubella exanthem certainly demands careful consideration of the circinate type of erythema multiforme.

COMPLICATIONS

Aside from the damage done in early pregnancy, the complications of rubella are exceedingly rare. As in other virus diseases, the menstrual cycle may be disturbed. It may be delayed or brought on early according to our experience, but such disturbance is infrequent. A mild form of polyarthritis may follow a few days after the eruption has disappeared. Lindberg²⁸ observed this in 6 cases. The knees and feet were involved in 3 cases among children, and the fingers in 3 adult cases. A mild fever accompanied these joint involvements. Potter,⁴⁴ however, describes a polyarthritis in a woman that appeared on the third day of the eruption and involved the wrists and fingers, as well as the knees, ankles and feet, and was unaccompanied by any fever. Geiger²³ reported 36 cases of arthritis in approximately 180 cases of rubella in Arkansas. Simpson²⁴ reported polyarthritis of a mild migrating type in 25 of 72 patients with rubella in England, and Bennett and Copeman³⁷ noted this complication

in the British Expeditionary Forces in the same year. Gregg¹ states that many of the cases of rubella in the epidemic of Australia in 1940 and 1941 showed "rheumatic sequelae." Gölzow⁴⁶ reported a case of pancreatitis during the acute stage, accompanied by severe diarrhea and general abdominal pains, along with a rise in the blood diastase.

Thrombopenic purpura in the course of rubella has been reported in 10 cases. Pitten⁴⁶ gives an account of a case in a nine-year-old girl with no previous history of bleeding. There was thrombopenia with a prolonged bleeding time. Gunn⁴⁷ describes the case of a nine-year-old girl with a previous history of mild nosebleeds since the age of five but with no cutaneous manifestations. This case also showed a thrombopenia with a prolonged bleeding time, but the white-cell count rose to 13,000 with 79 per cent neutrophils. In both cases there was severe and protracted epistaxis with cutaneous purpuric lesions on the trunk and extremities. The spleen was not palpable in either case. Bleeding stopped in both on the sixth day, and uneventful recovery followed. Gunn⁴⁷ cites 4 other cases reported in the literature. During 1946 a total of 4 new cases of thrombopenic purpura were reported. Warren, Rogland and Potsubay⁴⁸ report 2 severe cases among soldiers at Fort Dix, both of whom gave negative family and past histories of bleeding tendencies. One followed two days and the other four days after the onset of rubella. Epistaxis, bleeding from the gums, gross hematuria, intestinal bleeding and a palpable spleen were present in both cases. Diminished platelet counts of 30,000 and 40,000 were found. In 1 case the platelets completely disappeared at one time, and the count remained as low as 62,000 at the end of fifty days. In both there was a prolonged bleeding time (30 minutes), as well as generalized petechiae over the skin. A complete recovery followed in five months in one case and in two months in the other. Fox and Walton⁴⁹ report 2 mild cases in children. The first occurred in a nine-year-old girl ten days after the onset of a mild case of rubella. The second was in a sixteen-year-old boy, occurring on the fifth day of a rubella that had begun with a temperature of 103°F. Thus, the severity of the rubella attack had no relation to the incidence of thrombocytopenia. In the first case the platelet count was 40,000, the bleeding time was over 45 minutes, and the petechiae were distributed over the body. In the second case the platelet count and bleeding time are not given, but red cells were found in the urine. The petechiae developed rapidly and spread over the entire surfaces of the extremities. The first patient recovered in three weeks, and the second in two weeks. The family histories and the past histories regarding bleeding tendencies were negative.⁵⁰

Rubella encephalitis has attracted considerable attention. It usually comes on between the second and the sixth day after the onset of the rash, and

it may be manifested as a mild meningoencephalitis or as an encephalomyelitis. Thus, the symptoms range all the way from headache and rigidity of the neck to coma and convulsions. There may be diplopia, bulbar palsies, thickness of speech, muscle twitching, weakness of the extremities and retention of urine. Merritt and Koskoff⁵¹ reported 4 cases, Barracough⁵² 2; Davison and Friedfeld⁵³ 6, and Jack⁵⁴ 1. Wingo⁵⁵ reported a case in a twenty-four-year-old woman who developed signs of meningeal irritation seven days after the onset of the rash. The spinal-fluid pressure was equivalent to 240 mm of water, and examination of the fluid revealed 40 lymphocytes per cubic millimeter. Diplopia appeared on the third day of this complication and persisted for four days. Bradford⁵⁶ described 2 cases of rubella meningoencephalitis from a British Naval Hospital, both of which showed a spinal-fluid count of 20 cells per cubic millimeter, with a marked preponderance of lymphocytes. One patient recovered in two weeks, and the other in three weeks.

Margolis, Wilson and Top⁵⁷ reported 14 cases of post-rubella encephalomyelitis that occurred in Detroit in 1942. They estimated that encephalomyelitis occurred at the rate of 1/6000 cases of rubella. This rate is not unlike that found in measles and chicken pox. In mumps, on the other hand, a benign meningoencephalitis occurs in approximately 10 per cent of cases when carefully looked for, whereas encephalomyelitis is exceedingly rare. These authors do not differentiate cases of meningoencephalitis from encephalomyelitis. Six of their 14 cases were mild and showed neurologic signs for only three days. There were 8 severe cases, in 4 of which the patients died. In these 4 fatal cases the patients did not survive for more than three days. Among those who recovered, 1 showed symptoms for eight days, 1 for ten days, and 1 for over one hundred and twenty days, the last had almost recovered when the paper was written, however. The spinal-fluid pressure was found to be equivalent to from 120 to 180 mm of water, and the cell counts varied from 8 to 500 per cubic millimeter, averaging 91, with mononuclears predominating. The authors present a protocol that includes their own 14 cases, as well as 37 others culled from the literature, with a combined mortality of 21 per cent.

A unilateral temporary retrobulbar neuritis with diminished vision in the affected eye has been reported by Owen and Greenway⁵⁸. This occurred in the course of "meningoencephalitis" developing five days after rubella in a twenty-six-year-old man. This was really an encephalomyelitis with inability to urinate for seven days. The headache lasted for four and a half days, but aside from these symptoms the patient was not extremely sick and was all well on the sixteenth day. Revilloid and Long⁵⁹ report a case of "polyneuritis" in an eight-year-old boy that developed ten days after rubella. There were

diplopia and marked weakness of the muscles of the extremities, with loss of tendon reflexes. Complete recovery followed in a few weeks. This case also appears to belong under encephalomyelitis. Hodges and Witner⁶⁰ report a total of 15 cases of neuritis following rubella, of which 3 were brachial.

The pathology of rubella encephalitis is described by Davison and Friedfeld⁵³. Autopsy disclosed perivascular infiltrations in the gray and white matter of the cortical convolutions, the brachium pontis, the superior cerebellar peduncle, the dentate nuclei, the cerebellum and the brain stem. In this respect the pathology does not differ from other encephalomyelitides.

The origin of the encephalopathies is unknown. One theory held by many is that some latent encephalomyelitic virus is aroused into activity by the virus of rubella. In support of this is the similarity of the symptoms, signs and pathology found in the rubella type and the types that follow measles, chicken pox and vaccinia. On the other hand, Putnam⁶¹ lays great emphasis on the vascular occlusions with thrombosis, which, according to him, form the basis of the pathologic lesions. In his opinion it is possible that some sort of allergic reaction associated with the establishment of immunity takes place whereby the clotting mechanism is disturbed. At any rate, the inflammatory reaction in the brain is not simultaneous with lowered capillary resistance in the skin, because the encephalitic manifestations appear not with the onset of the eruption but usually as it is subsiding or after the rash has entirely cleared up.

RELATION TO SECONDARY INFECTIONS

Although any concurrent infection may occur during or after rubella it does not appear that this disease in itself tends to predispose to other infections. This statement does not agree with the opinion of Hamburger,⁶² who presents charts from an Army hospital to support his contention that patients recovering from rubella show the same well recognized susceptibility of measles patients to streptococcal infections. His experience may well be due to the prevalence of streptococci in that hospital. I have reviewed 100 cases of rubella that occurred among patients convalescing from scarlet fever. There was no evidence of increased susceptibility to any of the complications incident to streptococci in their respective age groups. This is in marked contrast to measles in the convalescence of scarlet fever in which the incidence of suppurative otitis media is greatly increased in all age groups.⁶³

Humphrey and Ekermever,⁶⁴ reporting an epidemic of 305 cases of rubella in children, found tonsillitis in 15 cases, suppurative otitis media in 3 and suppurative cervical adenitis in 2. The last two complications are not given in relation to the tonsillitis. One is led to assume that all three complications were the result of a concomitant beta-

hemolytic streptococcus infection of a nonscarlet-fever-producing strain. In any event, the incidence of 1 per cent otitis media reported in this series is far lower than that found among children with scarlet fever or measles, to say nothing of a combination of the two. Florand and Fiessinger⁶⁴ described a case of streptococcal septicemia occurring six days after rubella. Bronchitis and laryngitis have been observed during the course of rubella, but in such cases these complications existed well before the onset of the eruption and were contracted independently of the rubella but were in no way enhanced by the disease. Indeed, it is safe to say that rubella does not offer any added danger to concomitant infections or pre-existing disease, with the exception of thrombopenic purpura and possibly a latent encephalitic infection.

(To be concluded)

BENJAMIN CASTLEMAN, M D, *Associate Editor*

EDITH E PARRIS, *Assistant Editor*

CASE 33251

PRESENTATION OF CASE

A twenty-three-year-old single woman entered the hospital complaining of blueness of the hands, face and feet.

No abnormality at birth or in development as a child had been noted, but her mother stated that as a child she had not played with other children very much and had always been "lazy." At the age of twelve a mild, dull pain in the chest, located to the left of the lower portion of the sternum, had been noticed. At that time a bluish discoloration of the face and hands was first observed. There were no associated symptoms that seriously incapacitated the patient, although she noticed that if she exercised as other children she had headaches and became blue and somewhat weak. These symptoms, however, did not prevent her from roller skating and dancing. The pain disappeared promptly, but occasionally thereafter she was aware of a slight, dull pain in the chest, without particular relation to any activity. In addition, she complained that the eyes frequently became "blood-hot" and that the cold aggravated the blueness of the extremities. A gradual clubbing of the fingers from that time was noted. Three years before admission the patient went to a physician with these complaints. She was told that she had a low blood pressure and was given some "pills," which she took without benefit, she did not, however, consider the symptoms severe enough to return. A year later she saw a dentist for bleeding gums and was referred to her physician for a blood examination, which was negative. Fourteen months before entry she attempted to join the WAVES and was told that everything was normal except for blueness, clubbing of the fingers and an abnormal chest film. She was referred by the Navy to a sanatorium, where extensive studies for tuberculosis were negative. At the time of admission the patient complained only of cyanosis and clubbing of the fingers and toes. She felt perfectly well, being able to exercise strenuously without ill effect other than an increase in cyanosis, which she thought had gradually become more prominent.

The past history revealed no serious illness. The patient had had mumps, measles and chicken pox

as a child. She had had occasional sinusitis and a chronic morning cough productive of a teaspoonful of sputum. The gums had always bled easily. There was no history of familial disease.

Physical examination on admission revealed a well developed and well nourished girl in no distress. There was a striking cyanosis of the face, hands and feet with severe clubbing of the fingers and toes. The conjunctivas were markedly congested, and examination of the fundi showed extremely dilated veins with tortuous arterioles. The throat was a dusky red. There were no abnormal pulsations in the neck. The chest was clear. The heart was normal in size. The pulmonic second sound was louder than the aortic second sound. No murmurs were heard. One examiner described an inconstant pulmonary systolic murmur. The liver and spleen were not palpable. The extremities showed good pulsations. Neurologic examination revealed a right knee jerk that was less active than the left.

The temperature was 99.6°F, the pulse 80, and the respirations 15. The blood pressure was 100 systolic, 80 diastolic, in the right arm and 95 systolic, 78 diastolic, in the left.

Examinations of the blood showed red-cell counts ranging from 7,100,000 to 8,790,000, with hemoglobins of 21.5 to 24.9 gm., and a white-cell count of 12,000, with a normal differential. The venous blood had an oxygen content of 16.7 and an oxygen capacity of 28.5 vol per cent, with a hematocrit of 69.7 per cent. The arterial blood had an oxygen content of 24.85 and an oxygen capacity of 27.7 vol per cent, with a hematocrit of 67 per cent. The oxygen saturation was 89.2 vol per cent. The circulation time with ether was 11 seconds and with Decholin, 23 seconds. The vital capacity was 3100 cc. Urinalysis was normal. An electrocardiographic tracing was normal.

X-ray examination of the chest revealed an extensive "flecky" area of increased density in the right middle lobe, mainly in the anteromedial segment (Fig 1). There was also a fine network of increased density in the left lung field laterally that was thought to be in the lingular portion of the left upper lobe. Both leaves of the diaphragm were well defined and showed good motion. The hilar shadows were normal. The heart was normal in size, shape and action. Fluoroscopy showed evidence of pulsations of the major branches of the right pulmonary artery somewhat farther away from the hilus than usual. The finer branches showed no abnormal pulsations. The hands and feet failed to show any evidence of pulmonary osteoarthropathy.

The patient's condition remained unchanged. On the sixteenth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR EARLE M CHAPMAN. A pulmonary murmur was heard. Does that mean that it was heard over

the lung or in the second left interspace? That is an important observation, and it needs clarification

DR RONALD C SNIFFEN The record is not clear on that point

DR CHAPMAN May we see the x-ray films?

DR STANLEY M WYMAN The film of the chest shows mottled density lying in the anterior medial segment of the right middle lobe as seen in the anteroposterior projection. It is seen in the lateral view lying in this triangle. There was said to be fine mottling in the lingula of the left upper lobe

making a diagnosis of an arteriovenous fistula of the lung, with secondary polycythemia

Only two other conditions have to be considered in the differential diagnosis, and they are congenital heart disease and polycythemia vera. The latter is excluded by the failure to find immature white cells or basophilia in the smear. Congenital heart disease is practically excluded by the entirely normal cardiac findings.

This rare disorder is often congenital but possibly traumatic in origin, and yet the few cases reported

FIGURE 1

I cannot be sure of that finding. I think it should be noted that there is a rounded, sharply defined shadow extending outward and downward at this point, coming down to this region, which suggests the pulmonary artery. The lateral view of the skull shows no definite abnormality.

DR CHAPMAN May I ask if pneumothorax was done and if a further definition of the mass was obtained?

DR SNIFFEN Pneumothorax was not done.

DR CHAPMAN This case represents a rare clinical syndrome that would not have been correctly diagnosed or treated ten years ago. Indeed, its diagnosis was missed on three occasions during the patient's life. The characteristics are so clearly set forth in this history that I have no hesitancy in

in the literature since 1938 seem to have established a group of symptoms and signs that should indicate the correct diagnosis. These are cyanosis, clubbing of the fingers and toes, and symptomatic polycythemia usually in a young person with a normal heart and an obscure pulmonary lesion by x-ray study. Some patients have a continuous murmur over the lesion if it is of the cavernous type connecting with the pulmonary artery.

The hazards of continuing with the lesion are that it may rupture and lead to sudden death in pulmonary hemorrhage, such as in the case described by Rodes¹ in 1938, which at autopsy showed three hemangiomas in the right lung and one in the left lung, or the patient may be incapacitated by the symptoms of anoxemia. Such were the

symptoms that led to the first successful removal of the right lung containing such a hemangioma in 1942

Since then several cases have been successfully operated on, and the patients have lost the cyanosis immediately after operation, the blood counts have returned to normal, and the symptoms have disappeared. Disappearance of the symptoms, however, depends on removal of the entire lesion and the absence of multiple arteriovenous fistulas.

There are some interesting data and clinical points in this case that I think deserve further comment. For instance, the bleeding of the gums and suffusion of the eyes and mouth are clinical signs consistent with a polycythemia, and yet they seem to have been overlooked as diagnostic signs. The pulse rate was slow, and this suggests that the cardiac output was normal, since according to Marey's law, a rapid pulse can be due to a low blood pressure and not to an increased venous pressure.

Having seen the x-ray film I place the lesion in the right lung rather than the left, although it is possible for such a lesion to exist on the left side as well.

Fluoroscopy showed, "evidence of pulsations of the major branches of the right pulmonary artery." That is why I was concerned with the so-called "pulmonary murmur" and with the decision whether it was a murmur over the heart. The history stated that no heart murmurs were heard and later that a "pulmonary murmur" was heard. To me, that means a murmur over the lungs. This sign has been described in some cases of arteriovenous fistula of the lung.

The oxygen saturation in itself could be a significant diagnostic procedure. The patient had a slightly slow circulation time, with an arteriovenous lung fistula or even in pulmonary congestion one could expect even greater delay in the blood circuit through the lung.

In conclusion, then, I believe that this case is characteristic possibly of a cavernous hemangioma type of arteriovenous fistula of the lung, and I assume that at operation perhaps all or part of the right lung was removed. It would be interesting to hear from others about the subsequent course.

DR SNIFFEN: Dr King, have you any comment?

DR DONALD S KING: The patient came to the sanatorium with a diagnosis of questionable tuberculosis and was sent to this hospital from there.

DR JOHN T QUINBY: I believe that I was the first to see the patient in the Out Patient Department with some of the fourth-year men, and I thought that she had congenital heart disease. I followed her after entry into the hospital. Preoperatively the hematocrit was 67 per cent and the oxygen saturation 89 vol per cent.

DR SNIFFEN: Is such cyanosis usual with a not very low oxygen saturation?

DR QUINBY: As I understand it, the cyanosis depends on concentration of the reduced hemoglobin. With a high total hemoglobin, an unsaturation of 6 or 7 per cent apparently leaves enough reduced hemoglobin to cause a dusky color. Another interesting problem is that the cyanosis and exertion limitation were progressive as the patient grew older, suggesting that the magnitude of the lesion was increasing.

DR CHAPMAN: I intended to comment on the presence of cyanosis. The oxygen saturation was low, — the normal figure should not be under 95 vol per cent, and in this case it was 89, representing slight diminution, — but this was compensated for by the polycythemia. In most patients with congenital heart disease when one third of the blood is shunted through from the venous to the arterial side, the reduced hemoglobin goes up from 1 to 4 vol per cent, and cyanosis becomes established. It is unfortunate that the volumes per cent of reduced hemoglobin were not available.

CLINICAL DIAGNOSIS

Hemangioma of lung

DR CHAPMAN'S DIAGNOSIS

Arteriovenous fistula of lung, with secondary polycythemia

ANATOMICAL DIAGNOSIS

Cavernous hemangioma of right middle lobe of lung

PATHOLOGICAL DISCUSSION

DR RICHARD H SWEET: As Dr Chapman has said, this is a characteristic entity. The correct diagnosis was made ahead of time in this case by the Medical Department and concurred in by the surgeons. At that time there had been only four or five such cases operated on successfully, at least according to reports in the literature. All of them, I believe, had been pneumonectomies with the exception of one patient of Dr Janes in Toronto. This case, which was bilateral, was successfully operated on in two stages. The case under discussion was a characteristic so-called "hemangioma," which I prefer to call an arteriovenous fistula. There was one enormous pulmonary artery, probably as large as the whole pulmonary artery should be normally, and there was a corresponding enormous vein, which led out from the middle lobe. In the middle lobe there were numerous dilated vascular channels. So far as I know this is the first case treated by lobectomy alone. Since then, by the way, we have had a similar case — a lesion in the middle lobe — in a child two years of age, who presented the same clinical picture and was cured by surgery. On visiting Dr Alexander's Clinic in Ann Arbor I recently discovered that there was a third such case with arteriovenous fistula in the middle lobe. It had been thought to be the first

one that had been resected because we had not published our two cases

DR SNIFFEN After removal the external surface of the right middle lobe showed a number of small blebs without pleural reaction. Three large vessels entered the lung at the hilus. One of these vessels followed the course of the anteromedial bronchus, and 2 cm beyond its origin it was broken up into a honeycomb of large anastomosing, vascular channels that occupied an area 9 by 4 by 3.5 cm in the medial

operated on suffered alarmingly of exsanguinating hemorrhages on the operating table. I therefore assume that the rapid reduction was due to blood loss. We are sensitive to that, and this patient did not suffer any appreciable loss of blood during the operation. I think that possibly this was responsible for the slow return of the hemoglobin to the normal level.

DR HOWARD B SPRAGUE Certainly, in peripheral arteriovenous communication, one would expect

FIGURE 2

portion of the lobe and accounted for the blebs on the external surface (Fig 2). The lesion was not encapsulated but showed no evidence of growth. The channels were lined by endothelium, with localized points of subendothelial fibrous thickening.

The postoperative findings are of some interest. Eight days after operation the hematocrit had fallen to 62 per cent, and the oxygen saturation was up to normal. The hemoglobin remained elevated. In the few cases that I have read about, such as the patient studied by Hepburn and Dauphinee,² the blood values, including the hemoglobin, had returned to normal in eight days. In the case under discussion about six months elapsed before the hemoglobin and red-cell count fell to normal figures.

DR SWEET Several months after operation the patient showed some reduction in the clubbing of the fingers, and she was no longer cyanotic. I think that one comment is of interest regarding Dr Sniffen's remark about the rate at which the hemoglobin returns to a normal level. Until this operation was done, — I have not followed the reports in the literature since then, — all the patients

enlargement of the heart because of the increased flow. We have to agree possibly to an increase in pulmonary venous pressure. Does it not mean that the right ventricle can stand increased circulation better than the left ventricle? There are so few of these cases that we have not been able to draw a conclusion, but I think that it is of considerable interest that this patient had an increase in flow.

DR SNIFFEN Another point in reference to Dr Chapman's remarks: it is stated in the record that the blood examination two years before admission was normal in this case. In Hepburn's case the patient had been followed carefully in a sanatorium, and at that time she had a normal red-cell count and hemoglobin. Only in the last year and a half did the hemoglobin and the red cells increase.

DR SWEET How about cyanosis?

DR SNIFFEN It was present.

DR SWEET When the blood counts were normal?

DR SNIFFEN Yes, presumably because of the arteriovenous shunt and before secondary polycythemia had become established.

DR CHAPMAN I should suggest that the lesion was expanding in type and becoming enlarged and that the degree of polycythemia was in relation to the size of the shunt. In this case, as the tissues became distended, there was more bleeding. It is an interesting point that Dr Sprague has made, and one that has been made in other cases. It is surprising how the heart can accommodate itself to this extra load.

CASE 33252

PRESENTATION OF CASE

A forty-nine-year-old stock clerk entered the hospital because of increasing difficulty in swallowing.

Six years before entry the patient had begun to have attacks of diffuse abdominal pain associated with nausea and vomiting and occurring at any time of the day or night, without relation to meals or to the type of food eaten. A "stomach operation for ulcers" performed at a local hospital had brought considerable relief of symptoms, but he continued to have some epigastric distress and occasional nausea and vomiting despite "ulcer diets." Eighteen months before entry he had a sudden attack of extremely severe abdominal pain, radiating to the right shoulder. He was rushed to a hospital and operated on for "perforated ulcer." The site of rupture was found with difficulty owing to adhesions from a previous rupture. The postoperative diagnosis was "duodenal ulcer." Six months before entry the patient began to complain of food "sticking in the throat" accompanied by a pain in the substernal region that he had never had before. These symptoms gradually increased in severity until three or four months before entry, when he became unable to take solid food except with great difficulty. Two weeks before entry, the patient consulted another physician, who had x-ray films taken and told him that he had a "growth deep in the chest." The dysphagia continued to progress until at the time of entry the patient could take "only coffee", everything else was regurgitated. He had lost about 25 pounds in the previous three or four months. He was in the habit of taking one or two alcoholic drinks and smoking ten or fifteen cigarettes daily.

Physical examination revealed a thin, pale man who had obviously lost weight. The voice was hoarse. He complained of pressure in the epigastrium, causing discomfort in the midsubsternal region. The heart, lungs and abdomen were clear.

The temperature was 100°F, the pulse 98, and the respirations 35. The blood pressure was 100 systolic, 80 diastolic.

Examination of the blood showed a hemoglobin of 12.2 gm and a white-cell count of 9100, with 65 per cent neutrophils. The nonprotein nitrogen was 23 mg, and the serum protein 4.6 gm per 100 cc, and the chloride 94 milliequiv per liter. A blood Hinton test was negative. The urine was normal.

A barium swallow revealed marked obstruction to the flow of thin barium in the midesophagus, caused by an oval, sharply defined mass, measuring 5 cm in length. The mass was attached primarily to the anterior and left lateral wall of the esophagus and involved a large part of the wall (Fig 1). No definite ulceration was seen. Small amounts of barium trickled slowly past the mass, but this was insufficient to fill the stomach for a satisfactory examination of that organ. The stomach appeared irregular in outline, and its folds were markedly swollen. There was no evidence of gastric resection. It was not possible to determine the presence of a gastroenterostomy. The duodenal cap was large and showed a large crater. There was no definite evidence of disease in the chest. The medial wall of the left main bronchus was poorly outlined.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR CHESTER M. JONES There is a remote possibility of a single diagnosis in this case, but I do not believe that one diagnosis can cover all the symptoms. The diagnosis of duodenal ulcer would explain the symptoms for the first five and a half years before entry. The patient was operated on twice, and ulcer was found. There were symptoms of perforated ulcer eighteen months before entry, with pain in the right shoulder of subphrenic origin, a duodenal ulcer was said to have been found. I suspect that the surgeon merely did a simple closure at that time. I believe that the patient had a duodenal ulcer.

Certain things are not clear about that diagnosis, particularly in relation to the symptoms, which never followed a typical ulcer pattern. The symptom that brought the patient to this hospital was difficulty in swallowing of short duration — six months. He had pain with the difficulty in swallowing, with substernal reference of pain, which is ordinarily accurate and usually localizes the level of the lesion. The fact that there was pain suggests ulceration, because stenosis alone causes fullness and regurgitation rather than pain.

On physical examination the patient had lost weight and the voice was hoarse, indicating at least a possibility of involvement of the recurrent laryngeal nerve, which suggests involvement outside rather than inside the esophagus. If this statement of hoarseness is correct and if the sign was of recent origin it should be taken into serious account. The patient had fever, again suggesting an ulcerating

process or a condition causing some inflammation of pulmonary tissue

The laboratory data are noncontributory except for a total protein of 4.6 gm per 100 cc, which I regard as simply the figure that one would expect from starvation

The x-ray films should be the source of information that will give us the clue to the probable diag-

proves it. Small amounts of barium trickled slowly past the mass, and although the examination of the stomach was not entirely satisfactory the organ appeared irregular in outline and its folds were markedly swollen. Whether that means that the x-ray men suggested that the patient had carcinoma of the stomach, I do not know. I should like to see the films. Obviously if a gastroenterostomy had

FIGURE 1

nosis. I am not under any delusions about the difficulty of making a correct diagnosis in this sort of case. I do not believe that it is necessary to make a correct diagnosis, and I suggest that what is most important is the decision to make a move to relieve the obstruction, whether or not the diagnosis is correct is entirely beside the point. On the other hand I realize that I am here to try to make a diagnosis, and I should like to register surprise that the x-ray examination as described showed midesophageal narrowing due to an oval lesion, which was sharply defined, measured 5 cm in length and was attached primarily to the anterior and left lateral wall. No definite ulceration was seen. That certainly suggests that there was not an ulcer, but I do not believe that it absolutely

been done six years before entry it was done for insufficient reason. The second operation was a closure, and therefore the x-ray film probably did not show anything diagnostic. The x-ray description is that of a large duodenal cap with a large crater. If there was a crater, there should have been an active duodenal ulcer, and I do not see how one can define it otherwise. Even if the ulcer was active, I do not see how it had anything to do with what was going on in the esophagus.

The question arises whether there was an intraluminal tumor involving the esophagus, whether it arose from the wall of the esophagus or whether it was entirely extraluminal, pressing on the esophagus. There is at least a remote suggestion in the last sentence of the x-ray report that the medial wall

of the left main bronchus was poorly outlined, also, the patient was hoarse, which may suggest extrinsic pressure on the left recurrent laryngeal nerve. I might add that I heard Dr Sweet recently discuss mediastinal tumors, and if I remember the diagnostic batting average from x-ray films was about 10 per cent correct, or 90 per cent incorrect, from the point of view of preoperative diagnosis. Is that right?

DR RICHARD H SWEET Yes

DR JONES I do not expect to do well from the x-ray films

DR SWEET That was a selected group, I might add

DR JONES This case is also selected

DR STANLEY M WYMAN There is either a crater in the duodenal cap or a pseudodiverticulum from the old ulcer. I did not fluoroscope the patient, but the film is consistent with a crater.

DR JONES We have no lateral films here. The trachea is in the midline. There is no displacement of the heart, and I do not know whether there is compression of the left bronchus in that area. Certainly, there is an obvious tumor, which again is interesting because of the magnitude of the defect. But it is not constant, and it seems to me that there is pressure rather than an annular constriction, which one ordinarily sees with an adenocarcinoma of the esophagus. The stomach shows simply a picture of what is ordinarily considered a gastritis with thick rugal folds.

I should say that this was a tumor that was not intraluminal. I do not believe that it was carcinoma of the esophagus. On reading the history my first impression was that of esophageal cancer. I do not believe that the patient had an esophageal ulcer—a lesion that occurs at a lower level. This may have been a tumor arising in the wall of the esophagus with barium coming down on one side. Perhaps it was intraluminal.

DR WYMAN In this area the mass presses in on the column of barium, the barium flowing to the right. One must consider a mass arising in the wall of the esophagus as well as something pressing on the esophagus. I do not want to mislead Dr Jones. Perhaps I have said something I should not have said.

DR JONES You apparently helped me, but I need it. The point I make is that wherever one looks here there is evidence of esophageal wall on the right side and not on the left, which suggests compression where the barium runs through. It may arise from the wall of the esophagus itself. If that is the case, I suspect that it would go beyond the outer wall of the esophagus and encroach on the structures out here, possibly involving the recurrent nerve. I shall say that this was an in-

trinsic tumor of the wall of the esophagus, and I should not be surprised to find it slightly ulcerated.

CLINICAL DIAGNOSIS

Carcinoma of esophagus

DR JONES'S DIAGNOSIS

Tumor of esophagus arising from submucosal tissues

ANATOMICAL DIAGNOSIS

Leiomyoma of esophagus

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY Dr Sweet, will you tell us your findings?

DR SWEET Dr Jones gave an able discussion of this case. We were greatly puzzled by the severity of the symptoms. The x-ray appearance suggested more a benign tumor of the intramural type than a carcinoma of the esophagus. We were prepared from the history, as Dr Jones has said, to find that the patient had carcinoma of the esophagus, and then the x-ray films puzzled us. We likewise did not make any connection between this and the ulcer. Dr Richard Schatzki said that although he could not examine the stomach wall, there was something peculiar about the stomach, and he suspected carcinoma of that organ. We thought that the patient might have a carcinoma or lymphoma of the stomach, and we were going to investigate further. That had nothing to do with the esophageal tumor. At operation it looked like leiomyoma.

The tumor bulged through the musculature but it was easily removed locally. A myomectomy was performed. A biopsy had been performed previously in the muscular wall, and there was a point where I had to enter the lumen because the mucosa was so adherent. A portion of mucosa had to be excised with the tumor. I ought to say that it is extremely unusual for benign tumor of the esophageal wall to cause as much obstruction as this patient had.

A PHYSICIAN Why did he have pain?

DR SWEET Because he was so obstructed. The esophagus was almost completely shut off.

DR MALLORY Microscopical section showed a spindle-cell tumor, which we diagnosed as benign leiomyoma of the esophageal wall.

DR JONES Did the tumor press on any structures outside the esophagus?

DR SWEET No.

DR JONES What did you do with the stomach?

DR SWEET I think we shall take care of that some time soon, if the patient continues to show evidence of neoplasia there.

STREPTOMYCIN TREATMENT FOR TUBERCULOSIS

It was not long after streptomycin had been shown to have antibiotic activity against a variety of gram-negative and gram-positive bacteria, including *Mycobacterium tuberculosis*,¹ that experiments designed to determine its efficacy in experimental tuberculosis were undertaken. The first preliminary results in guinea pigs, which were reported by Feldman and Hinshaw,² indicated that streptomycin was well tolerated in these animals and that, even with the rather small doses and the short course of treatment used, it exerted a striking suppressive effect on the pathogenic proclivities of human tubercle bacilli. In a second series, this group,³ using somewhat larger doses, obtained re-

sults that were more striking, and it was shown that there was a reversal from positive to negative tuberculin sensitivity in more than a third of the successfully treated guinea pigs. These early results were considered to be at least comparable with those that they had previously observed with certain sulfones.

Several months after the first report the same workers⁴ made a preliminary report on their first nine months' experience in the treatment of human tuberculosis with streptomycin. The antibiotic was found to exert a limited suppressive effect, especially in some of the more unusual types of pulmonary and extrapulmonary tuberculosis. There was evidence to suggest a temporary inhibition of the multiplication of the organisms, but no rapidly effective bactericidal action could be demonstrated.

In another series of studies with streptomycin in guinea pigs, Smith and McClosky⁵ were able to show that the chemotherapeutic effect of streptomycin in less than one twentieth of the maximum tolerated dose was superior to that obtained with oral doses of Promin up to about half the maximum that these animals could tolerate. With a suitable combination of streptomycin and Promin they obtained results superior to any that they had previously observed. Others later found that streptomycin combined with Diasone, another sulfone related to Promin, exerted a synergistic or additive therapeutic effect in the treatment of experimental tuberculosis in guinea pigs.⁶ A similar superiority of combined therapy was demonstrated in experimental infections in rats.⁷

At about that time Youmans and McCarter⁸ showed that streptomycin exerts a marked suppressive effect in experimental pulmonary tuberculosis of white mice. Youmans⁹ also tested five highly virulent strains in vitro and found the lowest bacteriostatic concentration to be between approximately 0.1 and 0.8 units per cubic centimeter, but more than 50 units per cubic centimeter were required to exert a bactericidal action on 0.1 mg of these organisms.

It was soon demonstrated, however, that tubercle bacilli readily acquire resistance to streptomycin during treatment.¹⁰ Tubercle bacilli isolated from 8 of 12 patients after treatment showed marked resistance, in seven of these eight strains, the re-

istance had increased five hundred to a thousand times when compared with that of the strains isolated from the patients before treatment. These resistant strains were found to be as virulent for white mice as the original streptomycin-sensitive strains, and such infections were not suppressed by streptomycin.¹¹

The most extensive clinical trials that have been reported to date are those of Hinshaw and his associates.¹² The results that they noted in some types of cases were highly encouraging, but certain limitations of therapy also became evident.

Their first 100 patients included 12 with miliary tuberculosis, 9 of whom presented clinical evidence of meningitis. Only 4 of the latter survived, the periods ranging from two to ten months, and they were the only patients in the group to receive intrathecal as well as intramuscular injections of streptomycin. The cerebrospinal fluid returned to normal in only 2 of these cases. One patient who received a six-month course of treatment flared up after an interval of a month, indicating that infection may persist in spite of striking clinical improvement. More significant is the fact that all 4 survivors were left with severe neurologic damage.

Some evidence of improvement was also noted in cases of severe moderately advanced or advanced cases of active and progressive nonsurgical pulmonary tuberculosis. After treatment for two to six months definite roentgenographic improvement was observed in 25 of 32 such cases. In 12 patients there was evidence that pulmonary cavities had closed, but in 6 others thick-walled cavities persisted despite the treatment. Tubercle bacilli disappeared from the sputums of 13 patients, but in 15 others they persisted despite prolonged therapy. There was no demonstrable progression of the lesions in any of the cases. All those that were un-

improved had advanced lesions with thick-walled cavities of long standing. In 6 patients reactivation attended the discontinuance of treatment, but 2 of them promptly improved again when the treatment was reinstituted. Five of the patients had died at the time of the report, 1 of them had had a reactivation four months after a course of treatment carried out over a six-month period and failed to respond to

another course because the infecting organisms had become resistant.

Ulcerating tuberculous lesions of the respiratory tract, including the larynx, hypopharynx, trachea and larger bronchi, seem to have responded favorably in many cases. Tuberculous empyema, on the other hand, failed to improve following intrapleural injections alone in 4 cases, and only 1 of 3 others showed any improvement from

combined intrapleural and intramuscular treatment. In tuberculosis of the genitourinary tract the streptomycin appeared to have only a palliative action and was not considered to be a substitute for surgical measures when indicated.

The dosage that Hinshaw and his associates recommend in adults is from 1 to 3 gm daily in four or six intramuscular doses. They prefer sterile water as a diluent and use concentrations of 100 to 250 mg of streptomycin per cubic centimeter. For intrabronchial use or as an aerosol they advise concentrations of 25 to 100 mg per cubic centimeter, and for intrathecal injections they suggest 100 to 200 mg in 1 to 5 cc of cerebrospinal fluid or of physiologic saline solution every twenty-four to forty-eight hours. Prolonged treatment for at least two to four months is required. Untoward reactions, including fever, rashes and otic complications,^{13, 14} must be expected. They suggest that further treatment should be denied any patient in whom such complications arise and in whom the prognosis by conventional methods of therapy is good. They believe, however, that these reactions

are usually sufficiently mild to be disregarded in the progressive types of tuberculosis that are not amenable to other therapy. Most important, however, they emphasize that streptomycin is not to be regarded as a substitute for other and proved effective forms of treatment of tuberculosis.

Some preliminary observations by McDermott were summarized in the report of the National Research Council.¹⁵ His results also suggested that streptomycin exerts a definite action on the tuberculous process. This effect was most striking in hematogenous lesions. It was also noticeable in the exudative and moderate advanced type of tuberculosis but was less striking in cases with caseous lesions. Effects on central-nervous-system infections were impressive but not sustained. His more recent results are awaited with considerable interest.

Direct reports from the rather extensive program under way in the hospitals of the Veterans Administration are not yet published. A press release,¹⁶ however, indicates that the early results were favorable enough so that the program was extended to nineteen study units. About three fourths of the patients with pulmonary tuberculosis seem to have shown some improvement. The long-range effects are not yet known, and the incidence of relapses and of the development of resistant strains in this and other groups of cases will be helpful factors in determining the broader usefulness of streptomycin in pulmonary tuberculosis.

In the meantime variable results have been reported in isolated cases or small groups of cases of tuberculous meningitis in addition to those already mentioned. There was recovery, with apparent improvement in the neurologic findings, among 3 of 9 such cases.¹⁷⁻¹⁹ The use of streptomycin for prolonged periods seems indicated for cases of tuberculous meningitis and may be expected to yield some favorable results provided that treatment is given intrathecally and intramuscularly and that there are no coexisting caseous pulmonary or extensive intracerebral lesions.

From the point of the community as a whole, it is probably wise at present to limit the use of streptomycin entirely to the few clinics where carefully controlled and prolonged treatment and study are

possible. Only on the basis of the results in such controlled groups of cases may one expect to determine the real and permanent value of streptomycin in the various forms of tuberculosis and to recommend a nation-wide program for its use in individual cases and in groups of cases. General hospitals are not at present equipped to handle this problem and should not be expected to do so, and it is still too soon even to recommend a long-range program for specialized institutions. In the meantime it is hoped that more effective, less expensive and less toxic agents will become available, particularly ones with which the development of bacterial resistance is not such a prominent feature.

SURGICAL TRAINING

CERTAIN aspects of the future of postgraduate surgical training are brought out in a letter published elsewhere in this issue of the *Journal*. The problem is only another one of those that have been raised by a rapidly changing socioeconomic order and that have recently called forth many letters and editorials in medical periodicals. Adequate medical and nursing care, a sufficient number of hospital beds and efficient graduate training of all types have received consideration but it is often difficult to decide which is the cart and which is the horse.

The correspondent points out that the so-called "ward beds" in the teaching hospitals are for various reasons, becoming fewer and fewer and that the opportunities for the proper surgical training of interns and residents are consequently becoming poorer and poorer.

There is no doubt that the numbers of ward beds are lessening, and this will undoubtedly continue as various types of insurance covering hospital and medical care increase in popularity. The situation is further complicated by the fact that ward-plan subscribers to the Blue Cross who are also subscribers to the Blue Shield should rightfully be operated on by a participating surgeon rather than by a member of the house staff. Although it is acknowledged that in the interest of surgical training, by far the majority of ward patients in the large teaching hospital should be operated on by members of the resident staff, it is obvious that this is becoming increasingly difficult.

Another problem concerns the young surgeons who have completed their residencies and who unfortunately for themselves and for the communities in which they are needed, elect to remain in the large teaching hospitals. In such institutions these men are on service for periods of several months during the year, but if they are fair to the resident staff, "handing down" the bulk of the operative work, they get little return in practical experience from the amount of time that they devote to the hospital. On the other hand, the young surgeon who has had four or five years of active well supervised training fares little better if he goes to a com-

munity hospital unless he is fortunate or wise enough to choose a locality in which there is real need for a surgeon. As a rule his operative surgery is limited to what comes his way in private practice.

These trends appear to be inevitable and it seems obvious that the present system of postgraduate surgical training will not suffice and that it has a tendency to disrupt an equitable distribution of surgeons. Too few opportunities are available for postgraduate training furthermore too many well trained young surgeons remain in the large teaching centers partly because little incentive is offered for moving to smaller communities. Three possibilities as a means of relieving the situation are available — more widespread adoption of the fellowship or preceptorship as a method of surgical training, the development of community hospitals as teaching centers and subsidization of the young surgeon who locates in a small community. Other schemes will undoubtedly be devised as the necessity arises. Certainly efforts should be made to meet the demand not only for an increasing number of well trained surgeons but also for their equitable distribution throughout the country.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

CRABTREE — E. Granville Crabtree, M.D. of Brookline died May 30. He was in his sixty-fourth year.

Dr. Crabtree received his degree from Harvard Medical School in 1914. He was urologist at the New England Baptist and Beth Israel hospitals and consulting urologist at the Newton-Wellesley Hospital. He was a former president of the New England Urological Association and was president-elect of the American Urological Association. He was a member of the American Association of Genito-Urinary Surgeons, New England Obstetrical and Gynecological Society and New England Surgical Society and a fellow of the American College of Surgeons and American Medical Association.

His widow, a daughter and two sons survive.

GARFIELD — Walter T. Garfield, M.D. of Belmont, died May 31. He was in his sixty-sixth year.

Dr. Garfield received his degree from Harvard Medical School in 1909. He was emeritus professor of dermatology at Tufts College Medical School and was a member of the staff of the Boston City Hospital. He was chief of the Outpatient Clinic, Cambridge City Hospital and consulting physician at the Norwood and Long Island hospitals. He was a member of the American Academy of Dermatology and Syphilology and a fellow of the American Medical Association.

His widow, two sons, a sister and three brothers survive.

MUSSO — George H. Musso, M.D. of Lynn died March 1. He was in his seventy-third year.

Dr. Musso received his degree from New York University Medical College in 1898. He was administrator of the Union Hospital, Lynn.

CORRESPONDENCE

THE FUTURE OF POSTGRADUATE TRAINING IN SURGERY

To the Editor It must be apparent to all concerned with postgraduate surgical training that serious threats are arising to endanger the system as it exists today. Perhaps this system is not a desirable one, but its products have certainly brought an enviable reputation to American surgery throughout the world. Whereas gradual changes for the better should be a natural process of evolution in any system, it is envisaged that future changes for the worse are in store for this particular branch of postgraduate training.

The components that make up a well balanced surgical training program should give a man the opportunity to become familiar with the various preoperative and postoperative measures that are the most acceptable for any particular situation that may arise. He should have the opportunity to enter investigative work and to attend clinics and teaching sessions that are ably directed and designed to inculcate the principles of surgical anatomy, physiology and pathology. A pupil under such a well balanced program should become adept in handling patients and should become familiar with and able to execute various technics and maneuvers concerned with diagnosis and treatment.

One feature deserves special emphasis, since it should constitute a part of every program designed to produce a well trained surgeon. It is the *sine qua non* and at the same time the *bête noire* of all those seeking surgical training today. It is a feature with which training programs in medicine and its various specialties are not confronted to such a serious degree. This is the opportunity for a man to do various surgical procedures *himself*, under proper guidance. If this opportunity is lacking, failure is a certainty, no matter how well thought out and directed all other parts of the program may be.

This feature of surgical training aids both the surgeon and the patient. It benefits the surgeon in giving him a well rounded training, confidence in himself, coolness under trying situations and that intangible something called "judgment," which is the product only of experience. It benefits the patient by giving him expert surgical attention at a low cost. A young surgeon in training, with a good fundamental background, operating daily on major cases, will probably perform more ably in the average operation than the older surgeon who operates on the occasional patient in private practice. The former is subjected to closer scrutiny and to greater criticism, and this offers considerable stimulus to the average conscientious intern or resident.

Great upheavals in the social system of the world, and of this country in particular, are in progress. One of these is concerned with the redistribution of the wealth. One hears, and reads in various journals and newspapers, of socialized medicine, the Wagner-Murray-Dingell Bill and various insurance plans designed to raise the standard of medical care. The attempt of organized medicine to keep bureaucracy, political pilfering and graft from its doorstep is the natural reactionary development to many of these proposals.

It is quite doubtful that anyone could marshal an effective argument against the general ideas embodied by the Blue Cross today. Unquestionably, a great need was fulfilled by the development of this plan. What it may lead to, however, is another thing. Certainly, no business should be allowed the power to dictate policies that are not in the best interests of the medical profession.

There has been a noticeable trend in recent years of an increasing demand for private beds and a coincidental lessening of the demand for ward care. This is due to many factors, such as an increased national income, changes in the distribution of income and the growth of insurance plans. Some institutions have been forced to close off varying numbers of ward beds owing to a shortage of nurses, which is related in part to some of the aforementioned factors. Increased operational costs for hospitals have almost doubled the rates for ward care. The clamor for more private beds grows louder daily. In fact, at the present time, a plan is even being considered by which private patients would occupy ward beds. It is said that the objective of certain advocates of socialized medicine is to have multiple group practices, which would be financed by the state, with the assistance of federal grants. All patients under the care of such groups would be on a private or semi private status.

The term "ward beds" is used in reference to beds occupied by patients in a teaching institution under the care of the house and visiting staffs. No professional fees are paid by these patients. These beds are not necessarily free, although in some instances they are. If these beds are to be occupied more and more by private patients and those benefiting from employer's insurance, Blue Cross and the like, what beds are to be employed for teaching purposes? A possible answer is the fellowship system, which is used in various clinics throughout the country. This has a definite and highly useful place in graduate surgical training. The time for this type of training, however, is after a certain amount of fundamental and operative experience has been obtained, so that the various diagnostic and therapeutic technics executed by the highly trained surgeons in these great centers can be appreciated. It has been said that no matter how long one watches a great artist playing the piano, one can gain proficiency only by long hours of practice. The combination of watching and doing is the ideal one.

As the ward beds are encroached on by private cases, the will be fewer and fewer cases under the care of the house staff. Coincidentally, more and more men desire long training, stimulated by the requirements of the American College of Surgeons and American Board of Surgery. Thus the problem of adequate training for the young surgeon becomes increasingly difficult. No one will deny that increased training is a desirable thing, but where are the beds to train so many for so long? That would be difficult to answer in an event, but with the increasing shortage of ward beds it will become even more so.

The answer to these questions must be forthcoming soon. There are answers. The questions are not insoluble.

BOOK REVIEWS

Peptic Ulcer. Its diagnosis and treatment. By I. W. Helk, M.D., and A. Allen Goldbloom, M.D. 8°, cloth, 383 pp with 110 illustrations. Springfield, Illinois: Charles C. Thomas, 1946. \$6.50.

This monograph is unusual chiefly because it has been put together by two broadly trained internists who do not claim to be gastroenterologists. It presents a pleasant and easily readable account of peptic ulcer and its vagaries.

The general architecture of the book is along modern lines. The first chapter deals with the pathogenesis of ulcer, the second with pathology, the third with symptoms, and so on down to a discussion of the complicated ulcer and the indications for surgery—without mention, incidentally, of vagotomy.

The authors have been industrious, at the end of each chapter is a list of reliable bibliographic references, the illustrations are well chosen, and their literary style is plain and simple. Captain Herman Schildkrout—another internist without professed gastroenterologic leanings—has supplied a chapter entitled "Dyspeptic Soldier," which discusses functional indigestion with a fair degree of adequacy.

On the whole, the volume is simple and unpretentious. It makes no claim to educate the highly specialized specialist. Yet it is likely to prove a comfortable vehicle of information to the readers for whom it was written—the busy physician in general practice and the medical student who is preparing for tomorrow.

Lippincott's Quick Reference Book for Medicine and Surgery. A clinical, diagnostic, and therapeutic digest of general medicine, surgery and the specialties, compiled systematically from modern literature. By George E. Rehberger, M.D. Thirteenth edition. 4°, cloth, 1461 pp, with 302 illustrations. Philadelphia: J. B. Lippincott Company, 1946. \$15.00.

This popular, standard reference book, first published in 1920, has been thoroughly revised for this thirteenth edition. The sections on obstetrics, skin, eye, ear, nose and throat have been rewritten. Emphasis is placed on the clinical aspects of medicine. Part eleven consists of a large valuable alphabetical list of drugs with their dosage, solubility, method of administration, physiologic and toxic action and therapeutic indications. There is also a pharmacologic index arranged by classes of drugs, as well as a comprehensive

index of subjects. The volume is well adapted for quick reference and is suitable for public libraries. It is well printed in two columns, with a good type on good paper, and is substantially bound.

Practical Malariaology. Prepared under the auspices of the Division of Medical Sciences, National Research Council, by Paul F. Russell, M.D., M.P.H., Luther S. West, Ph.D., and Reginald D. Manwell, Sc.D. 8°, cloth, 683 pp., with 238 illustrations. Philadelphia: W. B. Saunders Company, 1946. \$4.00.

Raymond B. Fosdick, of the Rockefeller Foundation, in the foreword of this volume, describes malaria as "a stubborn disease, slow to kill, quick to incapacitate and hard to cure." This book is a balanced and authoritative study presenting the varied and complex problems of malariaology and setting forth the newer knowledge about this widespread disease. The experience and judgment of the authors are reflected in the thorough and competent treatment of every phase of the subject. Dr. Russell has devoted approximately twenty years to the study of this disease in numerous highly malarious areas of the world.

The clinician will find a concise description of the disease and the newer dosage schedules for prophylaxis and treatment that were developed during World War II. The new antimalarial drugs, chloroquine and paludrine, are also mentioned, along with the information available about results and usefulness at the time the book went to press. A short chapter on therapeutic malaria in the treatment of general paresis is given.

Since the specific diagnosis of this disease depends on the demonstration of parasites in the blood, the laboratory technician will appreciate the thorough descriptions of human and also animal species of plasmodia. Excellent colored plates of stained human malarial parasites in both thick and thin films are included. Technical methods for staining, preserving and culturing parasites are given, and procedures for handling, rearing and identifying mosquitoes are presented in detail.

After reading the thorough sections on epidemiology and control of the disease and its anopheline vectors, the reader will have no illusions about the simplicity of malariaology. Nevertheless, the community and technical problems of malaria control, the methods of attack and the results to be expected from control measures are applicable to a wide variety of malarial situations. The methods given for mosquito control and for drainage and filling of breeding places will be useful to public-health officers and sanitary engineers who are responsible for the general control of mosquitoes as pests, as well as for their eradication as vectors of malaria in endemic areas.

This volume is what the title indicates—a practical manual for use in the clinic, in the laboratory and in the field for the diagnosis, prophylaxis, treatment, control and study of malaria.

Handbook of Neurological Examination and Case Recording. By D. Denny-Brown, M.D. 12°, paper, 112 pp. Cambridge: Harvard University Press, 1946. \$1.75.

This brief manual is useful for house officers and students in a neurologic clinic. Since many manuals of a similar nature are available, it seems hardly necessary to add a new one. All the material contained in it is readily available in standard textbooks on neurology, where it should be. Although this book is sound, the need for it appears to be slight.

Operative Gynecology. By Richard W. TeLinde, M.D. 8°, cloth, 751 pp., with 309 illustrations and 9 color plates. Philadelphia: J. B. Lippincott Company, 1946. \$18.00.

This admirable textbook of operative gynecology is wholly in the best Hopkins tradition and derives lineally from the pioneer work of Howard Kelly. In a series of thirty-eight chapters, the author describes succinctly and with utmost clearness all the classic gynecologic procedures and a large number of new operative techniques, most of which he has himself devised. Each chapter is followed by a brief but expertly selected bibliography of references to the literature. The work is copiously illustrated with original drawings in black and white and fifteen subjects in full color on nine plates. The merit of the text is matched by that of the

illustrations, the majority of which are by James Didusch and the late Max Brödel. From every standpoint this is an exceptional book, which may be unhesitatingly pronounced the finest of its class to date.

Their Mothers' Sons. By Edward A. Strecker, M.D., Sc.D., Litt.D., LL.D. 8°, cloth, 220 pp. Philadelphia: J. B. Lippincott Company, 1946. \$2.75.

Some of the major issues with which psychiatrists concern themselves in their practice and study continue to be as baffling now as they were when man first surveyed man with the aim of improving his social condition and personal welfare. But much knowledge is being accumulated, and many wise persons are drawing their own conclusions about the material with which they work in this field.

One of these is Dr. Edward A. Strecker, who has spent the greater part of his life treating maladjusted patients and studying their problems. He has synthesized one of the results from this lifetime of labor into a simple formula that anyone can understand. It is the three letter word "Mom," first emphasized by Mr. Philip Wylie, but now given by Dr. Strecker the full stature and strength required to make it a living concept. Alfred Adler is reported to have said, "Children are the victims of their incessant mothers and their infrequent fathers." Perhaps this explains why Dr. Strecker fixes the blame on Mom instead of Pop. At any rate, the result of her sins of commission is the same as his sins of omission—an inadequate or maladjusted person who cannot work or fight and who seems incapable of learning to be a happy and useful citizen.

If anyone is an authority on this subject it is Dr. Strecker. He has practiced psychiatry in Philadelphia for years. He has dealt as a consultant with psychiatric problems in the Army and Navy. In the course of his work Dr. Strecker has made prolonged and minute investigations of countless cases. In all this, he has been profoundly impressed by the relationship of the mother and child and its effect on the child's performance and accomplishments later in life. Starting with an absolutely open mind or perhaps with an inclination to favor the interests and influence of the mother, Dr. Strecker concludes that at least one type of neurotic life pattern is due more to her than to anybody else. After reaching this conclusion, he devotes a great part of this extraordinary book to a description of what a Mom is and is not and to a detailed analysis of what such mothers do to their children and how they do it. This book is a self-administering text, by means of which any woman who suspects herself of being a Mom can soon find out the awful truth one way or the other. Dr. Strecker even goes farther and gives the reader some indication of what to do about it. For once and for all, Dr. Strecker presents a new and dynamic concept that is already proving useful in home and school where the danger of Momism is greatest.

This book will also be helpful to the physician who has a Mom to deal with. At least it will provide information in terms of Dr. Strecker's analysis. One question that comes up is, "What is a Mom?" The answer, according to this book is, "Mom is a mixed up mother who mixes up her child." This mix-up can occur anywhere along the line, but it may occur early and is usually maintained throughout the years when the child is in closest touch with the mother and most receptive to the impression of unfavorable as well as favorable features of her personality. Some would call it a vitriolic book. Perhaps it is. It is a book that may jolt some mothers into seeing themselves as others see them—particularly psychiatrists. But it is certainly not a book to give as a present on Mother's Day. Dr. Strecker should write a companion volume on Pop.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

THE SURGICAL TREATMENT OF URINARY INCONTINENCE*

MARSHALL K. BARTLETT, M.D.†

BOSTON

THE subject of exertional incontinence in women—or “stress incontinence,” as it is frequently called—has stimulated the imagination of the medical profession for many years. Numerous operative procedures have been devised for the cure of this condition, but as yet no entirely satisfactory technic is available.

This study was stimulated by the work of Dr. William T. Kennedy,¹⁻³ of New York. His results were so far superior to those previously attained that they could not fail to arouse interest.

Up to the time this study was undertaken, the usual procedure employed at the Massachusetts General Hospital for the correction of exertional urinary incontinence was by means of a repair of the anterior vaginal wall and a figure-of-eight or mattress stitch placed at the bladder neck, after the method advocated by Kelly⁴ in 1914. Discarding the untraced cases, Kelly's report showed 41 per cent cures. Our experience with this method gives essentially similar results. Cure may be expected in about half the patients on whom it is used. This is far from satisfactory, and in the uncured group the result is most disappointing to both patient and surgeon.

MECHANISM OF URINARY CONTROL

Much work has been done to determine the exact mechanism of urinary control in women. Careful and detailed anatomic study has been devoted to this subject, and excellent presentations by Kennedy,^{2, 3} Davies⁵ and Curtis^{6, 7} have appeared in recent years. From this mass of detailed work, certain fundamental facts appear that may be used as a basis for an understanding of the problem of urinary incontinence.

The wall of the urethra contains involuntary muscle fibers that become more numerous in the region of the bladder neck, where they are arranged in a circular manner and form what is called the in-

ternal sphincter. This mechanism is under autonomic control and under normal conditions serves to maintain closure of the bladder outlet.

There is also a voluntary sphincter mechanism, which consists chiefly of the sphincter urethrae membranacea. This muscle is contained between the two fascial layers of the urogenital diaphragm, which bridges the anterior portion of the pelvic outlet running from one ischiopubic ramus to the other. The fibers of the sphincter urethrae membranacea arise from the inner surface of the inferior pubic ramus and from the investing fascial layers and encircle the urethra. Posteriorly, they blend with the deep transverse perineal muscle to encircle the vagina. The sphincter urethrae membranacea is innervated by the perineal branch of the pudendal nerve, and its action is to constrict the urethra, making possible the voluntary interruption of the urinary stream.

The anterior fibers of the levator ani arise from the inner surface of the superior ramus of the pubis, and as they run posteriorly to insert into the coccyx, a few fibers are given off to the urethra. The importance of these fibers in contributing to the voluntary sphincter mechanism has been stressed by some authors.

If the mucous membrane is elevated from the anterior vaginal wall and care is exercised to keep the dissection close to the mucosa, an avascular plane is encountered, and a firm fibrous layer is uncovered. This is the pelvic fascia, and as the dissection is carried forward toward the external meatus, the region of the urogenital diaphragm is exposed (Fig. 2).

MECHANISM OF URINARY INCONTINENCE

When a patient with stress incontinence is examined in the lithotomy position, the urethra, instead of pointing almost horizontally, usually assumes a nearly vertical direction. This sagging of the urethra and bladder neck away from the pubic arch, which was emphasized by Watson⁸ in 1924, results from a tearing of the layers of pelvic fascia between the bladder and the anterior vaginal wall.

*Presented at the annual meeting of the New England Surgical Society, Worcester, Massachusetts, October 4, 1946.
†From the Gynecological Service, Massachusetts General Hospital.
Instructor in surgery, Harvard Medical School; associate visiting surgeon, Massachusetts General Hospital.

and the structures of the urogenital diaphragm. The displacement of the bladder neck and urethra impairs the function of the sphincter mechanism, leading to stress incontinence.

Whether the functional impairment of the sphincter mechanism is due to actual muscular damage to the sphincter urethrae membranacea or to loss of fixation of the urethra and its descent from a normal

FIGURE 1

An incision has been made in the anterior vaginal wall. The bulging of the anterior vaginal wall proximal to the external meatus is due to the sagging of the urethra and bladder neck.

position behind the pubic arch has not been established.

Under normal conditions the sphincter urethrae membranacea serves to allow voluntary interruption of the urinary stream. Its action is not normally required to prevent the involuntary escape of urine from the bladder even under conditions of stress and increased intravesical pressure. This function is fulfilled by the involuntary sphincter mechanism. It is my belief that stress incontinence occurs when the bladder neck and urethra sag away from their normal positions behind the pubic arch, because this results in a stretching and distortion of the bladder neck and proximal urethra that render ineffective the action of the internal (involuntary) sphincter.

The success of an operative procedure for stress incontinence depends on the replacement of the urethra and bladder neck in their normal positions, by whatever means attained, rather than on the reapproximation of voluntary muscle fibers. The importance of this restoration of normal anatomic relations in providing a good functional result has been emphasized by Kennedy.⁹

METHODS OF REPAIR

A great many surgical procedures have been devised for the cure of exertional urinary incontinence in women. They fall into three general types

The first comprises attempts to reconstruct the existing structures of the urethra or bladder neck, or both, by means of a vaginal plastic procedure. These vary from the simple Kelly⁴ stitch described above, and many modifications thereof, to more elaborate operations, such as that described by Kennedy¹⁻³ and Frost.¹⁰ Kennedy's technic is based on the concept that, in addition to the displacement of the urethra and bladder neck described above, the function of the voluntary sphincter has been impaired by the formation of scar-tissue bands between the urethra and the pubic rami laterally. To correct this, the vaginal mucosa is elevated from the bladder neck and posterior two thirds of the urethra, and the dissection carried laterally under the pubic rami until the urethra is entirely freed of its lateral attachments, including any post-traumatic scar tissue that may be present. The urethra is then plicated in the midline to restore the function of the voluntary sphincter. Kennedy obtained excellent

FIGURE 2

The mucous membrane is elevated. In the midline the layers are adherent, and the cleavage plane is indistinct. As the dissection is carried laterally, close to the mucosa, a good avascular plane is encountered, which may be easily followed laterally to the pubic rami. The pelvic fascia is revealed as a smooth glistening layer, and as the dissection is carried anteriorly toward the external meatus, the region of the urogenital diaphragm is exposed.

results by this method, reporting 35 cases with cures in 32.

The second general type of operative repair involves the use of various muscle or fascial transplants. Some of these procedures are done entirely from below, and others, partly vaginally and partly suprapubically. Portions of the levator muscles, the gracilis, the pyramidalis, strips of fascia from the rectus sheath or external oblique and various other

structures have been used. Recently, Price,¹¹ Aldridge,¹² Meigs¹³ and Studdiford^{14, 15} have reported excellent results through the use of a fascial sling

muscle of the trigone in the transvesical repair of the internal sphincter has been stressed by Macky.¹⁶

A nonoperative method for the treatment of stress incontinence was reported by Murless,¹⁷ who employed periurethral injections of a sclerosing solution (5 per cent sodium morrhuate). By this technique he was able to produce cures in 60 per cent of a series of 20 cases.

MATERIAL STUDIED

In the selection of cases for this study, the choice was limited to patients in whom the condition was believed to result from the trauma of childbirth. Patients who were nulliparous or in whom some congenital abnormality was present were not included.

Sixty-three operations for the relief of stress incontinence were done on 62 patients. Of these, 15

FIGURE 3

The pelvic fascia and urogenital diaphragm are approximated over the urethra and bladder neck.

This method seems to offer a means of replacing the bladder neck in its normal position behind the pubic

FIGURE 4

The pelvic fascia and urogenital diaphragm are reinforced by a second row of sutures.

arch when such replacement might be impossible to attain otherwise.

The third procedure employs the transvesical approach for the repair of the sphincter mechanism at the bladder neck. The value of recognizing the

FIGURE 5

Sutures are placed to close the mucous membrane and to anchor it to the underlying fascia. (This anchoring of the mucosa to the fascia has since been omitted.)

had had one or more previous operations for the same condition without success. These operations were done between 1939 and 1942, and it was believed that a follow-up study, after a period of over four years, would be of value. Of the cured patients, 12 could not be traced, and the follow-up period in these cases averaged fourteen months. The remaining 32 cured patients were traced, with an average follow-up interval of seventy months.

OPERATIVE PROCEDURE AND RESULTS

In the first 42 cases the technique described by Kennedy was followed as closely as possible. In this group 29 patients, or 69 per cent, were cured.

The stripping of the lateral attachments of the urethra from the pubic rami was then discontinued for two reasons: the dissection may result in considerable hemorrhage, from damage to the veins

about the bladder neck, which at times is difficult to control, and these lateral structures were considered to be the normal attachments of the pelvic fascia and urogenital diaphragm, so that their loss might interfere with the replacement of the bladder neck and urethra in the normal positions. Thus, in the last 21 cases the procedure resolved itself into the elevation of the vaginal mucosa from the entire urethra and bladder neck and a careful plication of

another case a cystocele occurred following the operation, and a later repair of this was necessary.

Three patients developed urethrovaginal fistulas requiring repair. It is believed that this may have been due to anchoring the mucosa to the underlying layer in the completion of the closure (Fig 5), and this procedure has been abandoned.

SUMMARY

The anatomy of the internal (involuntary) and the external (voluntary) sphincter mechanisms of the bladder and urethra in women are briefly described.

The relative importance of damage to the voluntary and involuntary sphincters in the production of stress incontinence is discussed.

Various operative procedures used for the cure of stress incontinence are briefly described.

Sixty-three operations were performed in 62 patients for exertional urinary incontinence resulting from childbirth trauma. The operation was successful in 44 cases, or 70 per cent.

Stress incontinence is believed to result when the function of the involuntary sphincter mechanism is impaired owing to stretching and distortion of the bladder neck and proximal urethra. This occurs after trauma that allows these structures to sag away from their normal positions behind the pubic arch. The voluntary sphincter may be damaged in the process, but such damage is of little, if any, importance in the production of stress incontinence.

The success of an operation for stress incontinence is considered to depend on the restoration of the bladder neck and urethra to their normal anatomic positions, allowing the involuntary sphincter to resume its normal function.

The mucous membrane is closed, thus completing the operation.

the pelvic fascia and urogenital diaphragm over these structures. This serves to support the urethra and bladder neck from below and to hold them up behind the pubic arch. The steps of this operation are illustrated in Figures 1 to 6. It is essentially the method advocated by Young¹⁸ in 1922. There were cures in 15 cases, or 71 per cent.

Various types of suture material were used in the repair, including catgut, cotton and silk. Little difference in the results was noted, although catgut seemed to be the best material, perhaps by virtue of a greater inflammatory reaction, with more scar-tissue formation.

A repair of the perineum was carried out in all cases to improve the pelvic support by approximation of the levator ani muscles.

One patient in each of the above groups was changed from being only improved to being cured by the use of periurethral injections of 5 per cent sodium morrhuate. The same treatment on a number of other patients who were not cured gave no improvement.

Complications

One patient developed a perivesical hematoma that became infected and required drainage. In

DISCUSSION

DR. EDWARD L. YOUNG (Boston) I should like to emphasize what I believe to be the cause of at least 30 per cent of the failures in this type of operation. These cases must be studied intensively beforehand, because there are many conditions that may make trouble. One is called a "reno-vesicle reflex" — a complicated name for something that is not understood, but it means that because of minor damage to the kidneys there are often bladder symptoms, including incontinence. Infection, which occurs in spite of a perfectly clear urine that is chemically normal, can also cause incontinence.

I believe that some failures are due to the fact that these conditions are not recognized. Last year I had an interesting case of failure. I closed what I was sure was a stress incontinence, and the patient was worse when I got through than before I started. I discovered that urine was draining from the cervix. Further study showed that the patient had had a supravaginal hysterectomy. The surgeon had carefully put a suture through the cervix and the bladder, where there was a valve. When the valve opened the urine poured out through the cervix.

I believe that about every quarter of a century this subject must be studied because it is a bothersome problem to a great many women and the best method is careful dissection, such as that described by Dr. Bartlett, to identify the layer that is a mixture of fascia and muscle tissue. If the cases are selected, I think that the cures will approximate 85 per cent.

DR. STEPHEN RUSHMORE (Boston) I have been interested in this subject for many years, and after operations for this condition I have found so many failures that I hope I have learned something from my experience.

In the first place, a satisfactory test of where the difficulty lies can be made by the use of a Pezzer catheter — not an old one from which the life of the rubber has been boiled out, but a new one that has some rigidity. If such a catheter is introduced and drawn down against the internal meatus of the urethra, the opening of the bladder, it can usually be determined easily that that is the point at which the weakness exists and at which resistance must be built up.

It seems to me that the cause of the failures in many of these cases is the fact that the sphincter muscle — the smooth muscle that is the wall of the bladder and is hypertrophied at this point — is stretched throughout its whole circumference, owing to injury at childbirth. If it is stretched more on the anterior or upper margin, there will be greater difficulty in repair of the organ or the structure so that it will function properly.

If the muscle is stretched at that point, the logical approach seems to be to repair it from above, an impractical method of attack. But that explains I believe, why sewing it up from below in some cases gives such a poor result, because the muscle itself has been weakened at the anterior and upper margin.

I think that the results may be improved by careful plastic operation and placing of sutures — it is the placing of the suture that is of greatest importance — and the testing of the amount of contraction resulting from the operation by the use of the Pezzer catheter.

In some of these cases in elderly women there is the trauma of many childbirths, and the tissue seems to have lost its tone, the muscle itself has lost most of its tone and is extremely flabby. A perfectly satisfactory functional result with a muscle that is practically exhausted cannot be expected in every case.

INFECTION CAUSED BY *STREPTOBACILLUS MONILIFORMIS**

Report of 2 Cases Following Rat Bites

LAWRENCE KILHAM, M D †

BOSTON

INFECTION due to *Streptobacillus moniliformis* is often characterized by fever, a migrating polyarthritides, a skin rash and a relapsing course. A preceding history of rat bite within ten days is frequent. In a few reported cases, however, no source of infection could be established.^{1,2} Place, Sutton and Willner³ described an outbreak occurring in Haverhill, Massachusetts, following the ingestion of raw milk. Organisms isolated from 11 of 13 patients in this epidemic were extensively studied by Parker and Hudson,⁴ who described them as a new species, *Haverhillia multiformis*. Unknown to them at the time, however, Levaditi and his associates¹ had isolated and described the organism a year previously as *Str moniliformis*. The most complete review is that of Brown and Nunemaker.⁵ Watkins⁶ recently summarized 39 cases of rat-bite fever reported in the United States in which *Str moniliformis* was the proved etiologic agent. Positive blood cultures were obtained in the 2 cases described below.

CASE 1. C. J., a 5-month-old infant, was admitted to the hospital on January 29, 1940, after having been severely gnawed by a rat. Physical examination showed a pale infant with a temperature of 102°F, regular respirations and a rapid pulse. There were bites on the right cheek and a large defect in the right wrist, in addition to tooth marks over the right hand.

The right wrist was debrided and irrigated. During treatment pieces of cartilage floated up through the defect. A culture of the wound grew out *Str moniliformis*, as did a blood culture taken on admission. Examination of the blood revealed a red-cell count of 2,220,000, with a hemoglobin of 43 per cent, and a white-cell count of 18,000, with 43 per cent neutrophils, 52 per cent lymphocytes, 4 per cent monocytes and 1 per cent basophils.

The temperature fell to 100°F in 3 days. After a week the temperature alternated between normal and 100°F until discharge. Chlorinate dressings and irrigations were applied to the wound daily, with steady healing and improvement, in spite of an x-ray diagnosis of osteomyelitis in the underlying bones. A blood Hinton test was negative on March 1. On April 28 the patient was sent to a convalescent home.

It is of interest in this case that in spite of extensive rat bites, from which *Str moniliformis* was cultured directly, and an early bacteremia, the disease did not progress to a full picture of rat-bite fever. No skin rash or polyarthritides was noted.

*From the Mallory Institute of Pathology, Boston City Hospital.
†Assistant in bacteriology, Harvard Medical School.

CASE 2 P S, a 75-year-old Jewish man, was admitted to the hospital on June 14, 1946, because of fever. A rat had bitten him on the forehead 3 days previously. On the day of admission the patient had fever, chilly sensations, headache, backache and pains in the knees.

Physical examination revealed a well developed and well nourished man lying comfortably in bed. Physical examination was essentially negative except for injection of the conjunctivas and a dry, coated tongue. No skin rash was present. The small wound on the forehead had healed. There was no tenderness, swelling, redness or pain on motion of the joints.

The temperature was 100°F, the pulse 84, the respirations 40, and the blood pressure 120/76. Examination of the blood revealed a hemoglobin of 100 per cent (Sahli) and a white-cell count of 12,300, with 93 per cent neutrophils and 7 per cent lymphocytes. Urinalysis was negative.

The patient was given 40,000 units of penicillin every 3 hours. Within 24 hours he became asymptomatic. The temperature fell to normal within 3 days. Penicillin treatment was continued until June 23, the day of discharge.

On June 20 the white-cell count had fallen to 7900. Blood Hinton tests were negative on July 3 and on July 27.

The blood taken on admission was cultured in a meat-infusion broth*. Within 24 hours there was a fairly abundant growth of *Str. moniliformis*, as determined by the characteristic "fluff ball" appearance of the colonies and the presence of pleomorphic, gram-negative organisms on smear. Identification was further confirmed by agglutination tests. Antiserums previously prepared in rabbits against three strains of *Str. moniliformis*—two from patients with rat-bite fever and one from a rat—were used for this purpose. Agglutinations using the patient's organism as antigen were obtained in all three serums in a titer of 1:6400. Agglutinin absorption tests were set up to determine whether the freshly isolated strain was identical with the other three. Two of them proved to be identical with the patient's organism. The third strain was a distinctly different type.

Agglutination tests, in which the patient's organism was run against his own serum, showed a marked rise in titer of immune bodies. None were found on June 15, but the titer had risen to 1:160 on July 3 and to 1:320 on July 27. Parallel agglutination tests on the first two dates were negative with dysentery polyvalent, *Pasteurella tularensis* and *Brucella abortus* antiserums.

On first isolation the organism showed a pronounced virulence for mice. 0.5 cc of a 24-hour culture in 10 per cent ascitic broth, when injected into each of 5 mice intraperitoneally, led to death in 24 hours. After repeated transfers the mouse virulence was lost. The *Streptobacillus* was markedly pleomorphic in the peritoneal cavity, but appeared as short, gram-negative rods when isolated by smear from the heart's blood†.

A penicillin sensitivity test revealed that the organism was killed by an in vitro concentration of 0.0156 units per cubic centimeter‡.

Subsequent blood cultures on June 19 and July 3 showed no growth.

This patient did not show any of the characteristic clinical signs of rat-bite fever. Since massive doses of penicillin were begun within twenty-four hours of the onset of the illness, however, and since the *Streptobacillus* isolated was extremely sensitive to the drug, the absence of such findings is not surprising. The illness began after a characteristic incubation period following the rat bite. Isolation in pure culture and the demonstration of a significant rise in titer of agglutinins during convalescence demonstrated that the infection was caused by

Str. moniliformis. The course of the disease did not favor an attempt to isolate *Spirillum minus*.

The outstanding feature of infections due to *Str. moniliformis* is the predilection of this organism for synovial membranes, which results in a migrating polyarthritis. Arthritis is characteristic of spontaneous outbreaks of the disease in mice⁷. Budding⁹ has recently shown that the *Streptobacillus*, when inoculated onto the chorioallantoic membrane of the chick embryo, leads to pathologic lesions that are localized primarily in the joints. Joint involvement is not invariably present in this type of rat-bite fever, although it occurs in a high percentage of cases.

In the cases presented above the characteristic manifestations of rat-bite fever did not appear. The early institution of penicillin treatment may explain the short course in Case 2. In Case 1 it is possible that the organism was of low virulence. One may also speculate that in some cases the infection is limited to a mild bacteremia. This might be found if patients coming to a surgical outpatient department for rat-bite treatment were subsequently followed with blood cultures.

The efficacy of penicillin treatment in cases of rat-bite fever has been described by a number of authors. Altemeier and his co-workers¹⁰ and Wheeler¹¹ noted rapid clinical improvement with penicillin. The sensitivity of the organism in Case 2 puts it in the range of bacteria most susceptible to the drug, such as pneumococci and streptococci.

Contrary to the experience of Brown and Nunemaker,⁵ the culture of *Str. moniliformis* has not been found difficult. Meat-infusion broth is sufficient for blood culture on primary isolation. The best growth, however, is obtained in infusion broth with the addition of 10 to 15 per cent ascitic fluid. Within twenty-four hours the growth appears as large aggregates of colonies near the bottom, suspended in a clear liquid. The organism can be maintained on blood-agar plates incubated in a candle jar. Transfers at weekly intervals have been sufficient to maintain three different strains for several years.

In Case 2 the agglutination titers rose to 1:160 and 1:320, although the patient had apparently harbored the *Streptobacillus* for only a short time. Brown and Nunemaker⁵ concluded from a serologic study of the serums from 120 control cases that a titer of 1:80 or above was definitely diagnostic of infection with *Str. moniliformis*. The natural growth of the *Streptobacillus* as aggregates of colonies in broth is unsuitable for the performance of agglutination tests. Suitable suspensions of antigen were obtained when a twenty-four-hour broth culture was agitated in a shaker for thirty minutes at moderate speed.

"Rat-bite fever" is a term used to cover two separate infections—one caused by *Str. moniliformis*

*Acknowledgment is made to Miss Marion E. Lamb, bacteriologist, Boston City Hospital, for her helpful suggestions regarding the bacteriology in this case.

†This phenomenon has been described by Parker and Hudson.⁴

‡Test performed through the courtesy of Miss Clara Wilcox, Thorndike Memorial Laboratory, Boston City Hospital.

and the other by *S minus*. The diseases caused by these organisms may be clinically indistinguishable, owing to overlapping symptomatology. Both respond well to penicillin therapy. Dawson and Hobby,¹² supported in a discussion by Blake, have questioned whether the laboratory evidence has been sufficient in all reported cases to support a diagnosis of infection with *S minus*, since mice used for blood inoculations may naturally harbor the *Spirlillum*. It has been established by inoculations of parietic patients with *S minus*, however, that this organism can cause a disease in man with both skin rash and polyarthritis.^{13 14} One wonders, nevertheless, whether the *Streptobacillus* might not be found more often if properly looked for in cases of rat-bite fever. No case reports have been found in the literature in which both organisms were found. Brown and Nunemaker⁵ present evidence that *Str moniliformis* is the most frequent infecting agent following rat bite.

SUMMARY

Two cases of infection with *Streptobacillus moniliformis* are reported. The simplicity of culturing

this organism and of agglutination tests is stressed. Penicillin was extremely effective in 1 case.

SURGICAL TREATMENT OF DEGENERATIVE ARTHRITIS OF THE KNEE JOINT*

G E HAGGART, M D †

BOSTON

SINCE the conservative treatment of degenerative or hypertrophic arthritis of the knee joint had been disappointing at the Lahey Clinic, particularly in vigorous patients with unilateral involvement, a plan of surgical management was decided on, and in 1940 the results obtained in knee joints that had been operated on in 20 cases were reported.¹ Since then sufficient time has elapsed to evaluate the results in an additional 10 cases. The object of this paper is to discuss criteria for selection of patients for surgery, to present details of the operative technic and finally to report the results obtained.

Selection of Patients

The importance of careful selection of patients for knee-joint surgery, especially when joint function is maintained, cannot be too strongly emphasized. In each case a detailed medical examination is carried out, and if the physical status indicates that major surgery on the knee is feasible, in addition to the orthopedic survey, the patient is considered from the standpoint of his ability to co-operate

and to follow out tiresome and often painful exercises, and in particular, an estimate is made of his desire or drive to return to comparatively normal activities. Provided that the patient's physical condition permits major surgery on the knee and the other requirements are fulfilled, operation is advised. It is understood that of many patients who have degenerative arthritis of the knee joint, relatively few meet the standards for surgery as herein described. But if the cases are carefully selected on the basis of the points outlined, the results have been superior to those obtained with other methods.

In patients with unilateral joint involvement in whom the preoperative studies indicate an advanced destruction of the joint, the significance of these data is emphasized, the patient is advised to permit an arthrodesis if on joint visualization the preoperative impressions are confirmed.

Operative Technic

The knee joint was first explored through a medium parapatellar incision. Later, in patients with marked hyperplasia of the patella, a midline incision was employed, the patella removed by sharp dissection, and the remainder of the operation performed under excellent visualization. In cases

*Presented at the annual meeting of the New England Surgical Society, Worcester, Massachusetts, October 4, 1946.
From the Department of Bone and Joint Surgery, Lahey Clinic.

†Chief Bone and Joint Service, Lahey Clinic; acting orthopedic surgeon, New England Baptist and New England Deaconess hospitals.

with advanced degenerative changes that indicated possible arthrodesis, the inverted "V" incision in the capsule, as described by Coonse and Adams,² has been most satisfactory

In the planning of a surgical procedure for the treatment of degenerative arthritis of the knee joint, repeated clinical observations indicated that the following structures in particular were to be considered the hyperplastic synovial membrane, the patella, the articular cartilage covering the femur and tibia and marginal exostoses, and the menisci.

If definitely scarred and hyperplastic, the synovial membrane was removed from the anterior portion of the joint, together with the fat pad. In none of these patients was the posterior compartment explored. Likewise, when the menisci were degenerated, they were carefully excised back to the posterior attachment.

The patella was either markedly reduced in size or removed entirely. The clinical impression that the region of the patella was a source of injury was borne out by the gross and microscopical studies of Keefer et al.³ in pathologic studies of a hundred knee joints from 77 consecutive cases at autopsy. Death resulted from a variety of causes, and the cases were not selected on the basis of previous clinical findings, diagnosis or presence of symptoms in the joint. These authors found that anatomic changes were often observed at the points that, in turn, had been subjected to the greatest movement, weight and pressure. In particular, degenerative changes were described at the median horizontal facet of the patella and along the patellar groove of the femur. In other words, the two regions of the knee that generally exhibit degenerative arthritis are in relation to the patella.

After a careful review of the literature, notably the results obtained by Brooke,⁴ who excised the patella for comminuted fracture, it was decided and proved that the patella could be either reduced in size or entirely removed without impairment of knee-joint motion.

The remaining steps of the operation comprise removal of marginal exostoses and shaving down of the fibrillated cartilage over the articular surfaces of the femur and tibia. This cartilage is often markedly degenerated, and it should be shaved down to a firm base, the operator should ensure that there are no rough spots to cause irritation. In this connection Magnuson,⁵ in 1941, reported good results in a large series of cases in which synovectomy was not performed and in which the patella was never entirely removed. This author emphasized that "the success of the procedure depends on the complete removal of all mechanical irritants from the joints." I am in complete accord with this statement and for that reason believe that in patients with long-standing, pronounced chronic hyperplasia the synovial membranes should be

taken out and the patella either cut down or removed.

The joint capsule is closed with interrupted silk, the subcutaneous tissue with interrupted fine chromic, and the skin with wire sutures. Use of the last material permits the sutures to remain in place ten to fourteen days postoperatively, while active muscle exercises and motion in the joint are instituted. The resultant scars have been much less obvious than when the skin was closed with other types of sutures. Large, fluffy sections of gauze pads are placed about the knee, and a firm pressure bandage applied to the entire extremity. Initially, patients are more comfortable in a plaster cast, but return of joint motion is delayed in comparison with cases in which only a pressure bandage is utilized.

When an arthrodesis of the knee was performed because of advanced destruction of the articulation, a long leg plaster cast over a pressure dressing as described comprised the immediate postoperative fixation. Two weeks after operation the cast was removed, and a Stader unit⁶ applied, fixing the position of the femur to the tibia and thereby maintaining excellent contact of the bony surfaces. This remained in place six to eight weeks. When the unit was then removed, clinical union between the two bones was often apparent. Thereafter, the patient was ambulatory and walked in a long leg plaster cast, bearing gradually increasing weight until roentgenograms indicated that sufficient union had occurred to permit application of a long leg caliper. The brace was removed when fusion was firm.

After the report by McKeever⁷ on the use of cellophane, the possibility of employing this medium was considered for these operations. But because of the satisfactory results obtained on the program of therapy as outlined and particularly because of my uncertainty regarding the eventual state of the cellophane, I decided not to add this element.

Postoperative Care

In the average case motion was begun on the fourth or the fifth day. Patients with adequate muscle control, particularly if they had received adequate preoperative training in muscle exercise, began motion on the third day. In others, motion was begun later. In all patients the extremity was intermittently suspended just above the ankle region by a sling attached to an elastic cord from an overhead frame. This permitted relatively early active exercise with a minimum degree of discomfort. Local heat and light massage were routinely carried out. Weight bearing was started within two weeks, under careful guidance. In an average of 3 out of 4 patients, gentle manipulation of the knee joint was performed under intravenous Pentothal anesthesia within three weeks after operation. It was found that this step materially expedited

return of normal joint flexion With one exception there were no untoward reactions following this maneuver

Results

With the objective of maintaining knee motion, 30 patients were operated on, and in 5 additional patients an arthrodesis was performed. In each case only one knee was treated. The average age of this group was fifty-seven years. There were failures in 3 cases. One has already been reported as being due to the presence of a mixed arthritis¹, 2 patients did not co-operate in carrying out the postoperative exercise regimen. Of the 5 patients submitted to arthrodesis, a firm bone fusion was obtained in each knee joint. The follow-up period ranged from seventeen months to seven years, with an average of twenty-six months.

Of the remaining 27 patients operated on to improve joint function, all exhibited postoperative increase of knee motion. Normal active extension of the lower leg on the thigh was observed in all cases. The minimum range of flexion was 65°, whereas the maximum was normal. In this group, 21 patients had a normal range of motion. In every case the articulation was stable, and swelling of the knee was not observed. Twelve patients denied any symptoms referable to the joint, 8 reported intimate aching pain in the knee after exposure to severe cold and damp weather. Seven patients described intervals of apparently mild discomfort after a rest period preceded by marked physical activity.

In summary, all this group emphasized that they did not suffer severe pain and that their symptoms were in no sense comparable to those experienced before operation.

With the exception of a case previously reported, the follow-up roentgenogram showed essentially no change as compared with the immediate postoperative film, and in no case did the subsequent film reveal the pronounced degenerative arthritis evidenced in the preoperative roentgenogram.

* * *

In patients with pronounced disability due to degenerative arthritis of the knee joint, who had been selected on the basis of their physical fitness for operation and in particular for their willingness to co-operate with the postoperative regimen described above, and with the objective of maintaining knee motion, the surgical procedure detailed in the text resulted in marked amelioration of symptoms. In a smaller group of patients who were incapacitated because of marked destruction of the joint as shown at operation, arthrodesis resulted in complete relief of pain while allowing greatly increased physical activity. Over a follow-up interval ranging from seventeen months to seven years, observations on this group of 35 patients confirm the belief that the surgical treatment of degenerative arthritis deserves an important place in the physician's armamentarium.

with advanced degenerative changes that indicated possible arthrodesis, the inverted "V" incision in the capsule, as described by Coonse and Adams,² has been most satisfactory

In the planning of a surgical procedure for the treatment of degenerative arthritis of the knee joint, repeated clinical observations indicated that the following structures in particular were to be considered the hyperplastic synovial membrane, the patella, the articular cartilage covering the femur and tibia and marginal exostoses, and the menisci

If definitely scarred and hyperplastic, the synovial membrane was removed from the anterior portion of the joint, together with the fat pad. In none of these patients was the posterior compartment explored. Likewise, when the menisci were degenerated, they were carefully excised back to the posterior attachment.

The patella was either markedly reduced in size or removed entirely. The clinical impression that the region of the patella was a source of injury was borne out by the gross and microscopical studies of Keefer et al.³ in pathologic studies of a hundred knee joints from 77 consecutive cases at autopsy. Death resulted from a variety of causes, and the cases were not selected on the basis of previous clinical findings, diagnosis or presence of symptoms in the joint. These authors found that anatomic changes were often observed at the points that, in turn, had been subjected to the greatest movement, weight and pressure. In particular, degenerative changes were described at the median horizontal facet of the patella and along the patellar groove of the femur. In other words, the two regions of the knee that generally exhibit degenerative arthritis are in relation to the patella.

After a careful review of the literature, notably the results obtained by Brooke,⁴ who excised the patella for comminuted fracture, it was decided and proved that the patella could be either reduced in size or entirely removed without impairment of knee-joint motion.

The remaining steps of the operation comprise removal of marginal exostoses and shaving down of the fibrillated cartilage over the articular surfaces of the femur and tibia. This cartilage is often markedly degenerated, and it should be shaved down to a firm base, the operator should ensure that there are no rough spots to cause irritation. In this connection Magnuson,⁵ in 1941, reported good results in a large series of cases in which synovectomy was not performed and in which the patella was never entirely removed. This author emphasized that "the success of the procedure depends on the complete removal of all mechanical irritants from the joints." I am in complete accord with this statement and for that reason believe that in patients with long-standing, pronounced chronic hyperplasia the synovial membranes should be

taken out and the patella either cut down or removed.

The joint capsule is closed with interrupted silk, the subcutaneous tissue with interrupted fine chromic, and the skin with wire sutures. Use of the last material permits the sutures to remain in place ten to fourteen days postoperatively, while active muscle exercises and motion in the joint are instituted. The resultant scars have been much less obvious than when the skin was closed with other types of sutures. Large, fluffy sections of gauze pads are placed about the knee, and a firm pressure bandage applied to the entire extremity. Initially, patients are more comfortable in a plaster cast, but return of joint motion is delayed in comparison with cases in which only a pressure bandage is utilized.

When an arthrodesis of the knee was performed because of advanced destruction of the articulation, a long leg plaster cast over a pressure dressing as described comprised the immediate postoperative fixation. Two weeks after operation the cast was removed, and a Stader unit⁶ applied, fixing the position of the femur to the tibia and thereby maintaining excellent contact of the bony surfaces. This remained in place six to eight weeks. When the unit was then removed, clinical union between the two bones was often apparent. Thereafter, the patient was ambulatory and walked in a long leg plaster cast, bearing gradually increasing weight until roentgenograms indicated that sufficient union had occurred to permit application of a long leg caliper. The brace was removed when fusion was firm.

After the report by McKeever⁷ on the use of cellophane, the possibility of employing this medium was considered for these operations. But because of the satisfactory results obtained on the program of therapy as outlined and particularly because of my uncertainty regarding the eventual state of the cellophane, I decided not to add this element.

Postoperative Care

In the average case motion was begun on the fourth or the fifth day. Patients with adequate muscle control, particularly if they had received adequate preoperative training in muscle exercise, began motion on the third day. In others, motion was begun later. In all patients the extremity was intermittently suspended just above the ankle region by a sling attached to an elastic cord from an overhead frame. This permitted relatively early active exercise with a minimum degree of discomfort. Local heat and light massage were routinely carried out. Weight bearing was started within two weeks, under careful guidance. In an average of 3 out of 4 patients, gentle manipulation of the knee joint was performed under intravenous Pentothal anesthesia within three weeks after operation. It was found that this step materially expedited

pollen, but only after subsequent exposure. In animal experiments no anaphylactic reactions were observed unless the animals had previously been sensitized to the fava bean by means of feeding or by injection of extracts.

The exact mechanism of how the hemolysis is produced is not too well understood. Preti⁶ reports that even sucklings were afflicted when the mother or the wet nurse ate fava beans, and in his cases the mother did not necessarily present the symptoms herself. He also noted that the condition was rare in persons who ate fava beans regularly throughout the year, and he assumed that this was due to a desensitization.

The incubation time between inhalation or ingestion and the onset of the first symptoms may be one to three days or only a few minutes. Thus, McCrae and Ullery's⁷ patient stated that he became unconscious while walking through the blossoming fields.

The usual prodromal symptoms include fatigue, weakness, headache, pain in the upper or lower extremities, anorexia, nausea, vomiting, abdominal pain, diarrhea and, in severe cases, unconsciousness. From one hour to one or two days after these manifestations hemoglobinuria begins, with marked prostration and at times with shock. At the same time the skin shows an ashen-gray pallor simultaneous with a moderate jaundice.

Depending on the degree of severity there are, according to Gasbarrini, five different forms: the abortive form, which is characterized by headache, nausea, pain in the upper and lower extremities, pallor of the skin and mucous membranes and absence of hemoglobinuria, the mild form, which is characterized by these symptoms, in addition to moderate anemia, slight icterus, slight hemoglobinuria and, usually, spontaneous recovery within a week, in the grave form, which may be deadly and which strikes soon after the ingestion of fava beans, the patient presents extreme weakness and prostration, marked pallor and moderate icterus of the skin and scant and markedly bloody urine — children often suffer from diarrhea and vomiting of bile, the fulminant form, which principally affects children and presents a sudden and intense anemia and hemoglobinuria and in which death from shock frequently occurs within the first twenty-four to forty-eight hours, and the so-called "hemorrhagic form," which is characterized by petechiae and ecchymoses and is extremely rare and nearly always fatal.

On physical examination an enlarged spleen may or may not be found. The liver is often slightly enlarged and moderately tender. The other abdominal organs usually do not show any pathologic change. Except in the rare hemorrhagic form there are no cutaneous manifestations of hemorrhage. The scleras are moderately jaundiced, and the skin shows the combination of pallor and icterus

described above. The patient is usually apathetic and listless, and may be in profound shock.

The blood picture is that of a severe normocytic anemia and the hemoglobin may be as low as 20 per cent and the red-cell count as low as 1,000,000. Some anisocytosis, poikilocytosis and polychromatophilia are present, but neither spherocytes nor target or oval cells have been reported. The fragility of erythrocytes to hypotonic sodium chloride solutions is usually within normal limits. Tests for acid, mechanical and heat fragility^{9, 10} have apparently never been made in this condition.

In the initial stage the blood reveals a leukopenia, a neutropenia and a thrombocytopenia. Shortly thereafter leukocytosis begins, and the blood may even present a leukemoid picture. The platelets also begin to increase in number and may go as high as 900,000, which according to Preti⁶ gives the case a favorable prognosis.

The blood chemical findings usually indicate a markedly increased icteric index, a moderate to marked bilirubinemia and a negative direct and a positive indirect van den Bergh reaction.

The urine may vary from a slight pinkish discoloration in abortive cases to a deep brick red in the severer forms. It may contain a few red cells and usually reveals a +++ test for albumin and a number of casts. The guaiac test is often ++++. The urine and stool show a moderate to marked increase of urobilinogen, the stool is brown, and the urine may contain some bile pigment.

In spite of its stormy and alarming onset, favism is a comparatively benign disease. The majority of patients recover. The mortality rate is 8 per cent, death occurring either in the initial stage of shock or later from anemia. The clinical course is apparently not influenced by the amount of ingested beans, minimal amounts having led to quite protracted illness and large portions having been followed by rather speedy recoveries. McCrae and Ullery's⁷ patient required hospitalization for thirty-eight days, whereas Hutton's patient was out of bed on the fifteenth hospital day.

No treatment may be required in the abortive cases, but in the severer forms, the most effective therapy is the immediate institution of compatible blood transfusions. These transfusions should be repeated daily as long as hemoglobinuria and other evidence of erythroclastic activity are present. For the initial stage of shock adrenalin has been recommended. The obvious prophylaxis is for the hypersensitive subject to avoid ingestion of the bean or inhalation of its pollen.

In the following case transfusions of whole citrated blood resulted in recovery.

A 3½-year-old, American-born boy of Italian extraction was admitted to the hospital on July 29, 1946, with the chief complaint of "bloody urine" of 16 hours' duration. The history, as obtained from the somewhat panicky parents, revealed that on the evening prior to admission the child had expressed a desire to urinate but had stated that he

FAVISM*

A Short Review and Report of a Case

HENRY J. WHARTON, M.D.,† AND WILLIAM DUESSELMANN, M.D.‡

HUNTINGTON, NEW YORK

FAVISM is an acute hemolytic anemia following contact with beans or pollen of *Vicia faba*. It has been classified among the paroxysmal hemoglobinurias,¹ and manifests itself by the so-called "hemolytic syndrome," which, in view of its specific action on the red cells, might better be named the "erythroclastic syndrome." The main characteristics are a fulminant onset, jaundice, anemia and hemoglobinuria. Favism is probably an allergic phenomenon that is due to a hypersensitivity to the ingestion of the beans or to inhalation of the pollen of *V. faba*, a large yellowish bean of the lima-bean family.

The condition is exceedingly rare in the United States, although not infrequent in Sicily, Sardinia and southern Italy. Apparently, only 2 cases have been reported in English, and these occurred in Italian-born adults who had immigrated to the United States.² The case reported below therefore appears to be the first case in an American-born child, although the patient was of Italian extraction.

Favism is a comparatively old disease. It was known to Herodotus, Pythagoras and Empedocles, and the condition is stated to have been quite widespread and grave, at times, in ancient Egypt and other Mediterranean countries.³ The first modern authors to report it were Messina in 1851, La Grega in 1856 and Di Pietra in 1858. The first to forward the idea that favism was due to an idiosyncrasy was Bertòlo in 1873.

An excellent paper about favism was written by Gasbarrini,⁴ who found a hereditary factor in about 20 per cent of cases. He observed that neuropathic, anemic and "lymphatic" persons were somewhat predisposed to the affliction. Gasbarrini refuted the theory of the older Italian authors that favism was caused by an infectious agent — possibly a fungous infection of the bean — and attributed the disease to a "toxin." A similar opinion was held by Fermi and Martinetti,^{4, 5} who reviewed 1211 cases.

Preti,⁶ who, as director of the University Clinic of Sassari in Sardinia, had ample occasion to observe a number of cases, maintained that the theory of a toxin was untenable because of the bizarre way in which the disease struck. He believed that favism was caused by an anaphylactic reaction.

The first of the cases in the English language mentioned above was reported by McCrae and Ullery,⁷ who described a rather severe attack of

hemoglobinuria and the usual symptomatology following the ingestion of fava beans in a fifty-three-year-old Italian-born man. In his youth the patient had had several episodes of unconsciousness while walking through fields of blossoming fava plants in Sicily, all these episodes had been followed by hemoglobinuria. After a diagnostic skin test this patient had a recurrence of some of the symptoms. The second case, reported by Hutton,⁸ occurred in a twenty-year-old Italian-born man who, besides the usual symptomatology, had a definite family history of occurrence in his grandfather, grandmother, mother and a brother. This patient gave a negative skin test.

The majority of cases have been reported from Sicily, Sardinia and the southern provinces of Italy. There are also a few reports from Germany.

Favism has quite a definite seasonal incidence, most cases being observed between April, the season of blossoming of the plant, and June to July, when the fresh, mature bean appears on the market. Gasbarrini⁴ noted that prolonged rain hindered the development of favism in a given year.

Heredity seems to play a definite role in about 20 per cent of cases. There are reports of entire families who are hypersensitive to the fava bean, as in Hutton's⁸ report. In the remaining 80 per cent no hereditary factor is evident. There is apparently no predilection for either sex, both being affected about equally. The majority of cases occur during childhood and adolescence, but the disease is by no means limited to the first two decades of life and cases have been reported in elderly people.

In the series of 1211 cases reported by Fermi and Martinetti,⁴ 459 were caused by inhalation of the pollen from the blossom of the plant, 725 were due to ingestion of the bean, and 27 had an undetermined etiology. Autopsies have been recorded in only 2 cases, in both of which the exact mechanism of the pathogenesis was rather inconclusive.³ Both examinations showed a generalized hyperemia and an increase in the size of the liver, the kidneys and the spleen. The spleen was reported as being three times its normal size in 1 case. According to Hoffman and Kracke,¹ a hypersensitivity to one of the protein substances present in the pollen as well as in the bean is created through repeated contact — either by inhalation or by ingestion — and is followed by destruction of erythrocytes, leading to the hemolytic-hemoglobinuric syndrome. The authors maintain that the syndrome does not occur on the first contact with the bean or its

fava beans or inhalation of the pollen is obtainable. In the case presented above, that of an American child with an emphatic denial of contact with *V. faba*, the diagnosis was not made at first. After all known erythroclastic (hemolytic) syndromes had been ruled out, an erroneous admission diagnosis of acute hemolytic anemia of the Lederer type was made, the diagnosis was changed only on the third hospital day, when a history of ingestion of fava beans was elicited.

Such an error is understandable, since the onset, clinical picture and clinical course of Lederer's anemia¹⁶ are similar to those in the case presented above, for that reason the disease has been called *anémie en coup d'archet* by French authors.¹⁷ It is quite possible that some of the less well understood of the 60 cases of Lederer's anemia reported in the literature^{18, 19} — whose etiology is unknown and was attributed by Lederer himself to an infectious process — can be explained by an allergic phenomenon similar to or even identical with that in the case presented above. Since fava beans are regularly eaten by a large number of people without producing symptoms, even in the person who may suddenly develop a marked erythroclastic process, it seems not improbable that a previous fava bean meal has been forgotten by the patient and escaped the attention of the physician.

SUMMARY

A case of favism that is apparently the first reported in an American-born child is presented. In two previous reports in the literature in English, both cases occurred in immigrants who had been born in southern Italy.

The diagnosis of favism was not made initially because the anxiety-stricken parents denied that the patient had eaten fava beans. This was ad-

mitted only on the third hospital day, after which the diagnosis was apparent.

The question is raised whether some of the obscure cases of acute hemolytic anemia of undetermined origin in the literature had a similar etiology.

In the case presented the onset of the condition was alarming, but the patient's response to daily blood transfusions was such that in eight days he was discharged from the hospital entirely recovered.

had pain in both knees and was too weak to walk to the bathroom. The mother had carried the child to the bathroom and had noticed that the urine was bloody. The family physician stated that the urine showed a +++ test for albumin but that he was unable to find any blood cells on microscopical examination. The bloody color of the urine increased in intensity during the night and the following morning, and the mother noticed that the skin had become somewhat jaundiced. The patient's general condition grew worse, he became more and more prostrated, and at noon, when he was admitted to the hospital, he appeared in extremis.

Both parents were exhaustively questioned about the past history in an effort to obtain a lead regarding the nature of the condition. They denied any instance of a similar episode in any of the close or remote members of the family at any time. There was no history of exposure to malaria, of syphilis or antisyphilitic treatment, of exposure to cold, of swimming at the beach, of any physical exertion, of sulfonamide or acetanilid medication or of contact with lead, other blood-destroying chemicals or carbon monoxide. There was no history of a spider or a snake bite or of ingestion of mushrooms or of fava beans. The child had been in good health since birth, no anemia having appeared before the present episode.

Physical examination revealed a well developed and well nourished boy who appeared to be moribund. He was extremely weak, apathetic, listless and, at the same time, irritable. The skin was both markedly anemic and markedly icteric, showing a combination of an ashen-gray pallor and a deep jaundice. The head was essentially normal except for moderately jaundiced scleras. The conjunctivas and other mucous membranes were extremely pale. The ears, nose and throat were essentially normal. There was no cervical or other adenopathy. The trachea was in the midline, the thyroid gland was not palpable. The chest was clear and resonant to percussion and auscultation, and there were no audible rales. The cardiovascular system presented a marked tachycardia (160 per minute), a regular sinus rhythm, no enlargement of the heart, no murmurs and no thrills. The heart sounds were of good quality. The abdomen was soft and nontender, and no masses were felt. The liver was slightly enlarged, the edge extending 1 cm below the costal margin, the spleen was not palpable. The extremities were essentially normal. The skin presented no pathologic changes except the discoloration described above. There were no petechiae, ecchymoses, evidence of insect or snake bites or interruption of the continuity of the skin at any place. The reflexes were physiologic.

The temperature was 102°F, the pulse 160, and the respirations 30.

Examination of the blood showed a red-cell count of 1,140,000, with a hemoglobin of 4.2 gm (29 per cent), and a white-cell count of 20,500, with 72 per cent neutrophils, 24 per cent small lymphocytes, 2 per cent monocytes, 1 per cent eosinophils, 1 per cent basophils and 1 per cent normoblasts. There was slight anisocytosis and moderate polychromatophilia. The platelet count was 248,000. The bleeding time was 90 seconds, and the clotting time 150 seconds. No spherocytes or target, oval or sickle cells were seen. There was no latent sickling. The mean corpuscular volume was 91 cu microns. The reticulocyte count was 4.2 per cent. The blood group was AB, and the patient was Rh+. A fragility test showed initial hemolysis at 0.44 in the patient and at 0.40 in the control and complete hemolysis at 0.28 in the patient and at 0.32 in the control. The icteric index was 57 units. The van den Bergh test showed a negative direct and a positive indirect reaction. A stool was negative for blood but positive for bile. The urine revealed an increased urobilinogen and some bile. It was positive for albumin and negative for sugar, and the sediment showed many coarse granular casts. The guaiac reaction was + + + +, but no red cells were found in the urine.

It was evident that there was, not hematuria, but hemoglobinuria, which is, of course, nothing but the urinary manifestation of marked red-cell destruction, and consequently a hemolytic or erythroclastic syndrome whose origin was obscure. A hemolytic crisis of a familial congenital hemolytic anemia was ruled out by the absence of spherocytes, of an enlarged spleen, of a pre-existing mild anemia and of a positive family history.¹¹

The blood picture was neither that of a Cooley's anemia (thalassemia or Mediterranean syndrome) nor that of a sickle-cell anemia,¹² the latter being considered as a possibility because it occurs occasionally in patients of Italian extraction.¹⁴ The condition was too acute and too alarming for a Marchiafava-Michele syndrome, and from the history, black-water fever, cold hemoglobinuria, march hemoglobinuria, favism or toxic hemolysis of any known mechanism could be excluded. The only condition that seemed to fit this case appeared to be Lederer's anemia,¹⁵ a condition that has often been misused as a catchall for hemolytic syndromes that cannot otherwise be classified.

Fortunately, on the 3rd hospital day, the mother, who had recovered from her initial panic, remembered that on the day of the onset of the disease the child had had a large meal of fava beans. She admitted that she had "forgotten all about it" owing to the excitement about the child's alarming condition. Consequently, the diagnosis was changed from acute hemolytic anemia of the Lederer type to favism. This revelation did not affect the therapy or the clinical course in any way, since the treatment for both conditions is identical.

Immediately after admission a transfusion of 300 cc of whole citrated blood was given. Toward the end of the transfusion the temperature rose to 106.8°F, following a chill of 10 minutes' duration and a convulsion lasting about 2 minutes. The pulse was 160, and the respirations went up to 60 and were labored. A moderate cyanosis was observed. The rise in temperature was probably a transfusion reaction, but because the diagnosis was uncertain it was considered advisable to administer 50,000 units of penicillin initially and 25,000 units every 3 hours.

On the following day the whole picture had changed rather dramatically. There was still the same amount of hemoglobinuria, with increased urobilinogen, and a + + + + guaiac reaction, but the temperature had fallen to 100.4°F, the pulse to 120, and the respirations to 40. The color of the skin was definitely improved, with less anemia and no cyanosis. The hemoglobin had risen to 7.6 gm (52 per cent), and the red-cell count to 2,400,000. The patient was less apathetic and began to answer when spoken to.

For 5 consecutive days 250 cc of whole citrated blood was administered daily with a consistent change in the blood picture (Table 1). The clinical condition continued to improve

TABLE 1 Significant Laboratory Data

5	4.1	12.2	84
8	4.7	13.1	90

rapidly, and the temperature fell to and remained at normal levels, the hemoglobinuria disappeared, the urobilinogen value becoming normal on the 4th day. The jaundice and anemia cleared up gradually, and on the 8th hospital day the patient was discharged.

An interesting feature in this case was presented by the spleen, which on the day of admission was not palpable. On the second hospital day a slight enlargement appeared, and on the third day the spleen was definitely firm and enlarged, the edge extending two fingerbreadths below the costal margin and being rounded. The size of the spleen remained unchanged until the sixth hospital day, when it became softer and decreased until it was no longer palpable on the eighth day.

The diagnosis of favism is said to be easy when it occurs in one of the usually stricken regions of southern Italy and when a history of ingestion of

with gross congenital deformities. This relatively low virulence in mortality of the fetus becomes a greater calamity through a relatively high morbidity with subsequent serious defects.

Congenital Anomalies

In 1941 Gregg¹ reported a series of 78 cases of congenital cataract in which 13 patients were seen in his own practice. A definite history of rubella during pregnancy was obtained in 68 cases, and in the remaining 10 there was a suspicious history of rubella, although a definite diagnosis could not be established. Forty-four children presented evidence of congenital heart lesions, and patent ductus arteriosus was shown at autopsy in 3 cases. A characteristic of many of these infants was that they were poorly nourished and presented difficult feeding problems. This discovery by Gregg resulted from his correlating the finding of so many congenital cataracts with the fact that a rubella epidemic of unusual proportions had been in progress in Australia in the preceding year. In looking backward for an antenatal explanation he found that this relatively minor exanthematous disease had been an almost consistent factor during pregnancy.

Under the direction of the National and Medical Research Council of Australia a survey was instituted under the direction of Swan and his associates⁷² in South Australia. Their report on 61 children, covering the period from 1939 to 1942, inclusive, revealed that 49 mothers who had suffered an attack of rubella during pregnancy gave birth to 31 infants with congenital defects. Among the mothers of these defective children, 29 had had rubella in the first three months of pregnancy, and the 25 who had had the disease in the first two months of pregnancy gave birth to infants with congenital defects. Four of the 8 mothers who had had rubella in the third month gave birth to congenitally defective infants. Two defective children were born of mothers who had had rubella after the third month. As opposed to the 31 defective children 18 healthy children were born of these 49 mothers. Four cases of congenital cataract were found in which the mother denied any history of an exanthem during pregnancy. The relation between the month in which rubella was contracted and the occurrence of congenital defects is demonstrated in Table 1.

As in the Gregg report the majority of the children were poorly developed and presented feeding problems. In this series, however, the cardiac defects predominated: there were 17 infants with heart lesions, and 14 with eye defects. Seven were deaf mutes, and 4 showed mental retardation. The defects frequently appeared in combination. Among the 17 patients exhibiting cardiac lesions there were 8 who also had cataracts and 2 who were also deaf mutes. These striking combinations were

revealed in later reports and constitute the suggestion of a syndrome of rubella effects.

Further reports from Australia by Swan and his associates,⁷³⁻⁷⁴ Gregg and his co-workers,⁷⁵ Evans,⁷⁶ Carruthers,⁷⁷ Welch⁷⁸ and Vickery⁷⁹ strengthened the conviction that rubella was an etiologic agent of prime importance in these congenital deformities.

Evans⁷⁶ investigated the dental abnormalities among the first group of children reported by Swan and his associates.⁷² In 34 infants whose mothers had had rubella during pregnancy there were 18

with dental defects of a major character, consisting of marked retardation of tooth eruptions, defective formation of the incisors and hypoplasia.

Carruthers⁷⁷ examined 17 of the cases of deafness found in the survey made by Gregg et al.⁷⁵ in New South Wales. The severity of the attack of rubella appeared to have no relation to the severity of damage in the ear. Most of the children gave some evidence of hearing over the tone range from 512 to 2048. Nine patients were given caloric labyrinthine tests with results that showed little deviation from the normal except that there was no vomiting even though nystagmus was induced. Post-mortem examination of one infant who died at the age of six and a half months and whose mother had suffered an attack of rubella in the first month of pregnancy disclosed underdevelopment, congenital cataracts and a patent ductus arteriosus. The ossicles of the middle ear were normal, but in both ears there was a total lack of differentiation of the primitive cells in the organ of Corti. Welch⁷⁸ supplied another study from New South Wales, covering 34 cases of congenital deafness in children born in 1938 to mothers who had had rubella in pregnancy. All these cases showed islands of deafness in the tone range.

From the pediatric point of view Vickery⁷⁹ studied the children of 20 mothers who had had rubella in the first three months of pregnancy. All were partially deaf and backward in speaking. Eleven were undersized and underweight. All infants presented problems in management, with sleeplessness and nervous irritability. Only 2 had congenital

Flibbertigibbet

In folklore congenital deformities were considered to be the result of extrinsic influences on the pregnant mother. Something she saw or some experience she underwent was thought to bring about the defect in her child. At the time when there was a general belief in witchcraft and calamities were ascribed to demoniacal influence, congenital deformities were supposed to be the result of the casting of a spell on the pregnant mother. *King Lear* contains the following reference: "That foul fiend, Flibbertigibbet. He begins at curfew, and walks till the first cock. He gives the web and the pin, squints the eye, and makes the harelip." The "web and the pin" is an old term for cataract. Flibbertigibbet was merely an unseen character referred to in a play, but people firmly believed in witchcraft in those days. The spell of a witch was thought to bring about all manner of ills to man and beast. Witch hunts were carried out to rid communities of those who were "possessed," as persons dangerous to the health of a community. The witch scare eventually subsided, but to this day the idea prevails to a certain extent that extrinsic influences can bring about congenital deformities.

The medical profession has been searching for intrinsic causes for these calamities in the newborn. Of late it has been shown that certain characteristics and congenital anomalies are derived from the genes. These include blood-group antigens, hemophilia and several other conditions,⁶⁸ and animal experiments have shown that a lack of vitamin A early in pregnancy can bring about cataract.^{66, 67} It now appears that prenatal infection can so disturb the development of the eye and other organs of the body as to cause gross deformities. The Flibbertigibbet of today responsible for at least some congenital defects seems to be the virus of rubella, which stalks unseen by day as well as by night in the house, the school-room and crowded places and which until recently was quite unsuspected and unfearful.

Miscarriage and Stillbirth

An obstetrician, Dr. Raymond B. Titus, asked me to see a primipara with a typical attack of rubella in the third month of pregnancy. The attack appeared to pass off in an uneventful manner.

*From the Harvard School of Public Health and the Haynes Memorial, Massachusetts Memorial Hospitals.

†Clinical professor of infectious diseases, Harvard School of Public Health, professor of clinical medicine, Boston University School of Medicine.

Six months later Dr. Burnet, of Australia, informed me of the dangers of rubella to the fetus. From Dr. Titus I learned that the patient had subsequently miscarried. At about that time a twenty-three-year-old primipara was admitted to my service at the Haynes Memorial with rubella. She miscarried on the sixth hospital day. Through the courtesy of Drs. Dwight L. Siscoe and C. J. Dunlop I learned of a patient who suffered an attack of rubella in the first half of the second month of pregnancy. Quickening was recognized after the fourth month and then ceased to be present. With failure of the uterus to increase in size the death of the fetus was determined. A macerated fetus was delivered in the seventh month. The mother has since been delivered of a healthy infant. A miscarriage in the third month of pregnancy after an attack of rubella in the second month has been reported by Swan and Tostevin.⁶⁸ On examination of the fetus a unilateral cataract was found. Goar and Potts⁶⁹ describe twins at seven months from a mother who had rubella in the first month of pregnancy. One was stillborn, and the other twin lived but had bilateral cataracts and a congenital heart lesion. A stillbirth with hydrocephalus in the seventh month of pregnancy following an attack of rubella in the first month has been reported by Fox and Bortin.⁷⁰ These authors, however, present another side of the picture, reporting normal twins and 2 other normal babies born of mothers who had rubella in the second month of pregnancy, 3 normal infants of mothers who had rubella in the third month, 1 normal baby whose mother had rubella in the fourth month and 2 normal babies from mothers who had rubella in the seventh and ninth months. All the normal infants were born at full term.

Thus, following an attack of rubella, the mother may miscarry, may be delivered of a premature stillborn child with deformities, may be delivered of a living child with serious congenital deformities or may go to full term and give birth to a perfectly normal child.

A more serious virus disease, smallpox, is known to cause miscarriage, and some French authors⁷¹ have found this to occur in 50 to 60 per cent of cases. In relapsing fever, which is a rickettsial disease, a fetal mortality of 92.4 per cent has been recorded.⁷² It is possible that the lower virulence of the rubella virus enables the fetus to survive more frequently, but such a survival may lead to the birth of a child

the various surveys of Swan, Gregg and their many associates. This compilation deals with the relation of the time of contraction of rubella during pregnancy and the birth of defective and normal children. It will be seen that in general this conforms with Table 1. The results are startling. When rubella occurred in the first two months of pregnancy there were 118 infants with congenital defects and only 4 normal ones, whereas when the attack of rubella took place in the last five months of pregnancy there were 6 babies with congenital defects and 20 normal ones. This indicates that during the

surveys. None of these, however, compare with the figures supplied from Australia. Nevertheless, the combined results add greatly to the evidence that rubella in the early months of pregnancy is a serious problem.

The subject of the normal babies born of mothers who contracted rubella during pregnancy seemed to be worthy of further investigation. I have therefore assembled these in Table 3, combining the figures already utilized in Table 2 with those derived from America, giving a total of 48 normal infants. The figures are again arranged by months

‡Figure supplied by obstetricians of California in answer to a questionnaire that concerned rubella only in the first three months of pregnancy

first two months of the life of the fetus there is an extraordinary vulnerability of certain tissues to the virus of rubella. This is less marked in the third month, with a ratio of 59.5, and in the fourth month, with a ratio of 28.4, and diminishes in the subsequent months of pregnancy.

It has been the custom to discuss these figures according to the trimester of pregnancy. The figures arranged in this manner do not give the startling results of the comparison of the first two months with the last five months because of the relatively small number of normal infants born to mothers who had had rubella in the last trimester. One would expect a much larger number, because in a consideration of the vulnerability of the fetus by trimesters, the ratio of normal babies should increase in inverse proportion to the number born with congenital defects. This is not apparent, and therefore it fails to confirm the startling figures of the first two months in comparison with those of the last five months.

Numerous reports have appeared from the United States and England. It is impossible to do justice to the detailed studies that have been made. With the exception of the survey by Fox and Bortin⁷⁰ in Milwaukee these reports confirm the findings in Australia. Some are simply isolated reports dealing with single cases, whereas others are valuable

as well as by trimesters. From these it is observed that 9 normal babies were found whose mothers had had rubella in the first two months of pregnancy as against 25 in the last five months. But if the entire period of nine months is divided into the three trimesters the figures are 17, 18 and 13 respectively. Here again, there is no inverse ratio of normal children to those with congenital deformities. The addition of Prendergast's⁸⁰ cases is necessary but confusing because the questionnaire sent out to the physicians in California asked only for information regarding babies born to mothers who had suffered rubella in the first trimester. The figures in Table 3, with the exception of the first month with 2 normal babies, lends no support to the figures of congenital deformities, which are strongly indicative of the vulnerability of the fetus in the early months of pregnancy. Indeed, these figures on normal babies tend to sustain the results obtained by Fox and Bortin.⁷⁰ If it is considered, however, that in the past five years there have been reports of only 52 normal babies born of women who had contracted rubella during pregnancy and that only 2 cases have been reported in which the mother had rubella in the first month of pregnancy, the negative evidence supplied in Table 3 and in the survey of Fox and Bortin fades before the overwhelming evidence against rubella. Especially is

cataracts, but 13 showed cardiac lesions with murmurs, precordial bulging and, on x-ray examination, left ventricular dilatations. In 1 case the ductus arteriosus was successfully ligated by operation.

A survey made by Gregg and his co-workers⁷⁵ revealed that the reported cases of rubella in school children in New South Wales from 1933 to 1943 showed a substantial rise to 1000 cases in 1936 and to 4683 in 1937. There was a sharp rise to 30,228 cases in 1940, and during that year 116

women were known to have contracted rubella in pregnancy, although the actual number is unknown. To these 116 women 117 babies were born, of whom 78 showed deaf mutism, 15 deaf mutism and heart disease, 4 eye disease, 4 eye and heart disease, 4 heart disease, and 6 deaf mutism and eye and heart disease. All these defects occurred in infants whose mothers had contracted rubella in the first four months of pregnancy, except for 8 cases in which the time of the attack was undetermined. The great majority of the defects occurred in cases in which the attacks had occurred in the first three months. In 1940 only 5 normal babies were found whose mothers had had rubella in pregnancy. The rubella occurred in the third month in 1 case, the fourth month in 1, the fifth month in 2 and the seventh month in 1. Two of the 116 mothers gave a history of an attack of rubella previous to the one in pregnancy. In addition, 20 cases from other years were included in this report, giving a total of 136 cases.

It will be observed that these Australian investigators have delved into the subject from many different angles. The question was raised whether this Australian epidemic was due to some mixed infection. A severe sore throat had been prevalent in Australia, but Swan and his associates⁷² showed that cultures yielded a predominance of *Haemophilus influenzae*. Furthermore, no correlation between the sore throats and the congenital defects could be

established. Thus, a mixed infection with symbiosis was eliminated. Next, the possibility of an unusual strain of rubella virus was considered. It must be kept in mind that this epidemic of 1940 took place during a war year, with troop mobilization in progress. It is well known that many diseases show acceleration in morbidity during military mobilization, and with such acceleration the virulence of the etiologic agent is often increased. Several of these authors remarked on the severity of the rubella attacks and the frequency of rheumatic sequelae. Nevertheless, the incidence and severity of the congenital deformities bore no relation to the severity of the attacks in the mother. Furthermore, reports from England²⁴ and the British Expeditionary Forces²⁷ described epidemic rubella with characteristics of similar severity at the same time. A survey made by Prendergast⁸⁰ of congenital deformities following maternal rubella in California yielded results similar to those reported from Australia, and it was suggested that the Australian strain had been introduced into California because of the close communication between the west coast of America and Australia during the previous five years. It appears that here again an accelerated morbidity due to intensive military mobilization was involved, during which an increased number of pregnant women contracted rubella early in pregnancy, as a result, 40 infants were found to have gross congenital deformities as against 4 normal babies whose mothers had contracted rubella in the first trimester of pregnancy. There seems to be no valid reason for supposing that the virus of rubella during epidemic conditions acquires any augmented powers of invading the fetus in utero. Epidemics merely offer the virus an increased opportunity to attack pregnant mothers. The Australian epidemic was of sufficient proportions to lead Gregg to his discovery of the causal relation of rubella to the congenital cataracts that came under his care.

The various reports from Australia come from independent investigations and surveys. Some of the investigations conducted by specialists deal with cases studied in the surveys. The work of Carruthers⁷⁷ on deafness was carried out on the cases covered in Gregg's⁷⁵ survey, and the actual number of cases with deafness was found to be greater than that in the survey. It is impossible, however, to include these additions in the survey figures. On the other hand, the studies of Evans⁷⁶ on the dental defects of the patient in the survey of Swan et al.⁷² can be incorporated under the survey without reduplication in the number of defects found in this group.

Each author or group of authors have studied the subject either from the point of view of a survey or according to the specialty of the author. There has been a decided lack of any attempt to unify the results. Table 2 presents the figures of

the various surveys of Swan, Gregg and their many associates. This compilation deals with the relation of the time of contraction of rubella during pregnancy and the birth of defective and normal children. It will be seen that in general this conforms with Table 1. The results are startling. When rubella occurred in the first two months of pregnancy there were 118 infants with congenital defects and only 4 normal ones, whereas when the attack of rubella took place in the last five months of pregnancy there were 6 babies with congenital defects and 20 normal ones. This indicates that during the

surveys. None of these, however, compare with the figures supplied from Australia. Nevertheless, the combined results add greatly to the evidence that rubella in the early months of pregnancy is a serious problem.

The subject of the normal babies born of mothers who contracted rubella during pregnancy seemed to be worthy of further investigation. I have therefore assembled these in Table 3, combining the figures already utilized in Table 2 with those derived from America, giving a total of 48 normal infants. The figures are again arranged by months

The figures in Table 3, with the exception of the first month with 2 normal babies, lends no support to the figures of congenital deformities, which are strongly indicative of the vulnerability of the fetus in the early months of pregnancy. Indeed, these figures on normal babies tend to sustain the results obtained by Fox and Bortin⁷⁰. If it is considered, however, that in the past five years there have been reports of only 52 normal babies born of women who had contracted rubella during pregnancy and that only 2 cases have been reported in which the mother had rubella in the first month of pregnancy, the negative evidence supplied in Table 3 and in the survey of Fox and Bortin fades before the overwhelming evidence against rubella. Especially is

this apparent when the combined figures assembled from the literature of Australia, the United States and England yield reports of 521 children born with serious congenital deformities during the past five years following maternal rubella. This is a ratio of ten grossly deformed children to one normal child, irrespective of the month in which rubella was contracted.

The details regarding these 521 congenitally deformed children are presented in Table 4. It will be seen that 359 of the cases occurred in Aus-

this has already been emphasized. I have left out several other deformities noted occasionally, such as an arachnodactyly, which is clearly hereditary, and cleft palate, which can be brought about by environmental modifications as well as by genetic mutations.⁸² There were 3 cases of pyloric stenosis, 2 of obliteration of the bile ducts, and 1 of spina bifida. These were all found in conjunction with the other deformities characteristic of infants born of mothers who have had rubella. That there were 3 cases of pyloric stenosis is of significance because

*In 10 of these cases the diagnosis was suspected but not definitely established.

Since the studies of Carruthers on deaf mutes were done in cases included in the series of Gregg¹ and the Evans studies on dental defects were done in the series of Swan et al.,⁷² which are summarized in the text, these reports are omitted.

†Most conservative use of figures given in order to avoid reduplication in reports of 80 cases from the State.

‡Diagnosis of rubella probable in 6 cases. Total number of probable diagnoses in this table is 22. Cases given as possible diagnoses have been omitted.

tralia, 110 in the United States and 52 in England. The further details are incomplete because many of the patients were examined by specialists in their respective fields,—for example, for eye or ear defects alone,—and some of these infants did not live long enough to reveal deafness, mental retardation or dental deformities. Among these children there were 221 with eye defects, 243 with deafness, 221 with heart lesions, 74 with microcephalus, 24 with mental retardation, and 20 with gross dental deformities. Actually, mental retardation was far more frequent than these figures indicate, since in numerous reports the statement is made that in "many" or "most" of the cases this defect was apparent. Often this was difficult to ascertain because of the existence of deafness or blindness, or both. Furthermore, it is futile to attempt to show the combination of these deformities, since

the finding of these defects among the 521 cases constitutes a high incidence.

It is interesting to note that in the survey made in Tennessee by Conte, McCammon and Christie⁸⁶ it was estimated that the rate of babies with congenital anomalies born of mothers who had had rubella in pregnancy was ten times greater than that for congenitally deformed babies in the population at large.

The finding of these congenital deformities following maternal rubella has naturally aroused interest in the possibility that other infectious diseases, particularly those of virus origin, will cause similar defects. In this respect the Australian investigators, Gregg and Swan with their respective associates, have shown particular interest. Deaf mutism, patent ductus arteriosus, microcephalus and pyloric stenosis have been recorded following

such diseases as measles,^{72 55} mumps, chicken pox and herpes zoster^{68 72} and influenza^{72 95} There is nothing as yet in the literature, however, to suggest that such diseases — with the possible exception of influenza⁷⁴ — compare with rubella in bringing about these congenital deformities, much less a syndrome of eye, ear and heart defects It is important to remember that these deformities may occur without any history of rubella Fox and Bortin⁷⁰ described a woman who in 1937, after a supposedly uneventful pregnancy, gave birth to an infant with bilateral cataracts, in 1945 she is said to have had rubella in the second month of pregnancy, after which she gave birth to a normal infant From my hospital experience I am aware of so many cases erroneously diagnosed as rubella that I cannot be too sure of the accuracy of the state reports on this disease The environmental influence of other infections on the fetus in utero needs the same concerted investigation that is being given to rubella

It must be kept in mind that these reports and surveys represent a backward approach to the problem As such, there is much that is unsatisfactory from an investigative point of view Although rubella is a reportable disease, it is often not reported, and as I have intimated above, it is frequently improperly diagnosed Any backward approach through cases reported to boards of health must take into consideration these possible errors of omission and commission Eventually, we shall have a series of pregnant mothers who have unquestionable rubella and are followed through, the incidence of miscarriages, stillbirths and the findings at autopsy, as well as of normal children and those born with congenital defects, along with the full details of such defects, being given Similar investigations must also be undertaken through the entire field of infectious diseases so that the position of rubella in this respect can be properly ascertained Until adequate studies have been carried out in this manner opinion must be based on such evidence as can be gathered by this backward method of surveys of rubella and of congenitally deformed children

To date the available evidence points to a 10 1 chance (521:52) that a woman who has rubella in pregnancy will give birth to a child with a gross congenital deformity, such as cataracts, deaf mutism, patent ductus arteriosus or mental retardation, and not infrequently with a combination of these defects The incidence of the deformities is in inverse proportion to the month of pregnancy in which the attack of rubella takes place Thus, the likelihood that such a deformity will follow rubella in the first and second months is the greatest It was first estimated at 100 per cent by Australian authors (Table 1) Later this was modified to 118 to 4 by our compilation of Australian surveys (Table 2) Utilizing the figures on normal babies (Table 3) alone, I should lower the estimate still more, but the mass of evidence points to a serious and startling

proportion of deformities — well above 10 1 This ratio changes with each month of pregnancy, and the danger of giving birth to a deformed child decreases to the zero point in the last month (Table 2) In the California survey of the first trimester only, the most conservative estimate was 40 deformed and 4 normal babies⁵⁰ From the Tennessee survey it was estimated by a rather roundabout method that the proportion of deformed children born to mothers who had rubella is ten times greater than the congenitally deformed children born of the population at large⁵¹

Against all this mass of testimony are the results of the survey made in Milwaukee by Fox and Bortin⁷⁰ This report deals with 12 babies born of mothers who had rubella during pregnancy, in 8 of whom the attack of rubella had occurred in the first three months Seven normal babies were born, including a pair of twins There was one stillbirth at the eighth month, and one "blue baby" with hydrocephalus, who subsequently became normal Of course these results differ from those in all the other surveys On careful analysis, however, one cannot agree with the conclusions of these authors, which imply that rubella presents no serious danger to the fetus Two of the children came very near to being badly deformed One died in utero late in pregnancy as stillbirth with hydrocephalus Had it lived the child would in all probability have been a mental defective The other was a "blue baby" with hydrocephalus who subsequently recovered and became "perfectly normal" There were, therefore, two very fortunate escapes among these 8 children, and this signifies a serious hazard in those 2 If the 6 cases in which rubella occurred in the first two months of pregnancy are considered, it might be stated that 2 of the 6 children barely escaped becoming seriously deformed These normal infants studied by Fox and Bortin are included in Table 3 to give the figure of 52 normal babies as a balance against the collected 521 grossly deformed children, giving a ratio for all months of pregnancy of one normal child against ten grossly deformed children — a formidable indictment against rubella and one deserving of special consideration under the treatment of this disease Added to this is the conspicuous demonstration that most of the deformities followed an attack of rubella in the early months of pregnancy Consequently, there appears to be little room for doubt regarding the serious danger of this disease to the fetus during the early months of gestation The evidence at hand, although unsatisfactory in several ways, is sufficient to warrant consideration in the management of this problem

CONGENITAL DEFORMITIES FOLLOWING ATTACKS OF RUBELLA BEFORE CONCEPTION

A curious phenomenon that has come to light is difficult to explain in a disease of such short duration as rubella Hall⁷⁹ reports the case of a child

born in 1942 with a congenital heart lesion, bilateral cataracts and complete deaf mutism, whose mother is said to have suffered a "sharp attack" of rubella six weeks before conception. Sweet¹⁰⁰ supplies the report of a woman who contracted rubella ten days before conception, the date of conception being fixed by the husband's three-day military leave. This pregnancy resulted in the birth of an infant that had bilateral cataracts, patent ductus arteriosus and hydrocephalus and lived only three months. The mother has since given birth to a perfectly normal child. In contrast are the 2 cases reported by Swan and Tostevin⁶⁸ in which rubella was contracted thirteen days and six days, respectively, before conception. This was figured out on the assumption that "ovulation occurs approximately fourteen days before the onset of the next menstrual cycle and that fertilization takes place within twenty-four to forty-eight hours of ovulation." It is interesting that in the first case a therapeutic abortion was carried out in view of the possibility that the child would be malformed. The specimen sent to the pathological laboratory consisted of fragments of tissue. Both eyes were intact, and further histopathological examination revealed no abnormality. The other patient went to term, and the child was normal.

TREATMENT

Aside from the problem of rubella in pregnancy, this disease is so relatively mild in the vast majority of cases that the natural recuperative powers of the body need no special help from the armamentarium of the physician. If fever is present bed rest appears to be indicated, unless the new notion of getting sick people out of bed captures the fancy of the modern doctor. Certainly, bed rest need not be enforced too strictly. One has but to be reminded that in another virus disease — namely, mumps — it has been clearly shown that the old notion of strict bed rest does not diminish the incidence of orchitis. It is highly improbable that complete rest in bed will diminish the rare complications of rubella. Most of the patients with mild cases do not stay in bed anyway and do perfectly well if they are permitted to be up and about. I had the opportunity of observing an epidemic of rubella in a regiment in a training area. The first 2 patients were admitted to a measles ward. After this affront, with the connivance of two superior officers, the subsequent patients remained on full duty. Those who were sick remained in quarters. The epidemic burned itself out without any sequelae other than a threatened court martial, which never materialized. This method of dealing with epidemics of rubella has been successfully carried out in lay institutions. During the Blitz in London, sadly needed beds for casualties were occupied by patients with rubella.

In 1814, when blood letting was in vogue, Maton⁶ gave due consideration to this form of therapy,

deeming it unnecessary in cases of rubella. He advocated nothing more than purgation. Paterson,⁷ in 1840, favored the fad of his day, recommending the application of leeches to the chin and sternum, as well as enough wine of colchicum to induce vomiting and purging. If constipation is present it needs gentle correction. A reasonable amount of activity of the skeletal muscles tends to avoid this condition and is preferable to overactivity of the smooth muscles of the entire gastrointestinal tract. If the eruption is accompanied by itching, which is rare, calamine lotion is indicated. Some physicians have found warm baths helpful. A little activity takes the mind off this minor disturbance. A good night's sleep can be achieved in a quiet environment without the aid of a narcotic. Gargles and nose drops are quite unnecessary.

It goes without saying that sulfonamides and penicillin are not indicated, and yet I have seen both generously applied, according to the spirit of the times, before the patient was admitted to the hospital. This is a pure waste of valuable medicines. The same thing could be said of the vitamins, there appears to be ample vitamin reserve to carry a patient through an attack of this disease. As a matter of fact, no one has the slightest idea of the relation of vitamins to resistance to rubella. Serum therapy is quite unnecessary for the ordinary case. Jacob Bigelow's¹⁰¹ address, "On Self-Limited Diseases," delivered before the Massachusetts Medical Society in 1835, is still good prescribed reading. In short, there is little that need be done except to make the patient comfortable, and since in the vast majority of cases the patient suffers not so much from discomfort as from the deprivation of his usual pursuits and activities, the possible advantages and disadvantages of imposing restrictions should be carefully considered. Before the recognition of the deleterious effects of rubella on the fetus in utero there was a growing tendency in various boards of health to remove all isolation requirements. In view of the newer knowledge of this disease this idea needs reconsideration. The treatment of the pregnant woman who suffers an attack of rubella is discussed below.

PREVENTION

Protection against rubella is like protection against an atom bomb, and can be summed up in one word — distance. If exposure could be avoided, the disease itself could, of course, be prevented. On the other hand, exposure to the disease in childhood appears to be advantageous, since an attack is likely to afford a lifelong immunity. Therefore, the proposition that it is advisable to have rubella in childhood advances the corollary that it is advisable for all children to be thoroughly exposed, which means the removal of all isolation precautions, so that as many children as possible can have the disease and thereby acquire immunity from sub-

sequent attacks. The fallacy in such a sweeping statement lies in the fact that many children in the community have mothers who are pregnant and who may or may not have had rubella — many mothers are ignorant of whether or not they have had it. It has already been pointed out that the immunity from one attack is not always permanent, it is only relatively permanent. Thus, the removal of precautionary isolation may entail the danger of rubella in pregnant mothers contracted from children exposed in kindergarten or school. Certainly, this contingency is to be avoided if possible, but it presents one of the most difficult problems. It is easy enough to say that all children should be inoculated with the virus of rubella, but an active virus would give rise to the disease itself, which would be communicable to others. Therefore, although it is safe to say that an epidemic of rubella should be allowed to run its course in asylums and boarding schools and in such colleges as can be isolated for the time being, the same statement cannot be postulated for day nurseries, kindergartens and day schools or colleges situated in metropolitan centers.

It has been pointed out above that this disease appears to be communicable just prior to the eruption and that communicability diminishes abruptly with the disappearance of the rash. Consequently, since the rash is of short duration, isolation for the eruptive period is effective for only about half the period of infectivity. Thus, the factor of time must also be considered in relation to distance in the matter of exposure.

Barenberg and his co-workers¹⁰² have offered presumptive evidence that the intramuscular injection of pooled serum or plasma will prevent rubella in children. The duration of such protection is unknown. This method could be utilized in children exposed to rubella whose mothers are pregnant. At the same time, larger doses could also be injected into the pregnant mothers. Just how reliable such an attempt at affording passive immunity would be in the event of a protracted epidemic, even though repeated doses were given, remains to be determined. One must take into consideration the possibility that such a serum will be contaminated with infectious hepatitis. Gamma globulin, which has been proved to be effective after exposure to measles and ineffective after exposure to chicken pox, is as yet an untried weapon against rubella. Until a vaccine of modified rubella virus that will not give rise to a communicable form of the disease and yet will afford a permanent immunity has been perfected, the complicated problem of protecting pregnant mothers from contracting rubella will remain.

TREATMENT OF THE PREGNANT MOTHER WHO CONTRACTS RUBELLA

It would be interesting to know whether pregnancy renders a woman more susceptible to rubella.

Apparently, the manifestations of rubella in the pregnant woman are no severer than those in other persons, thus, there is no real direct danger from the virus to the mother herself. Once exposure has taken place and the incubation period has passed and the rubella eruption has reached the stage where the disease can be recognized, there is the possibility — in the early weeks of pregnancy, the probability — that the virus has gained access to the fetus. Evidence has been presented pointing to the susceptibility, which is particularly marked in the first two months of life, of certain fetal tissues to the virus of rubella. This premise presupposes that the virus would attack the fetal tissues as soon as it became active in the mother, if not sooner. If the virus has already combined with these fetal structures the question arises whether any number of protective antibodies contained in antisera administered to the mother would preclude serious damage to the fetus. By the time the disease is recognizable in the mother it is highly probable that the virus would already have accomplished serious injury to the more susceptible embryonic tissues, and that no amount of antiserum could offset the damage. The administration of such an antiserum in any of its present forms would leave one with the uncertainty of its efficacy.

Threatened Miscarriage

Whether or not antiserum has been administered, any signs of miscarriage ought to be welcomed, and I can see no justifiable reason for any attempts to avoid such a favorable event. There is nothing in the dictates of the medical profession or in the common law of English-speaking countries that instructs a physician to attempt to prevent a miscarriage in the face of the evidence that has been presented. To bring up the religious motive of preserving life at all costs is on a par with the superstition of the Hindu who will not kill a cobra that attacks his own child because the cobra is a sacred animal.

Of course, a human life is sacred. Yet, under certain circumstances, one may take a human life in self-defense, both in peace and in war. A nation at war expends the lives of its citizens. Physicians are not bound to preserve life at all costs. Nothing is gained by saving a life when agony and anguish lie ahead, whether in the death throes of cancer or in the future birth of a grossly deformed infant. Because human life is sacred, there are exceptions to preserving it at all costs and under all circumstances. Physicians are now faced with a new exception. No attempt should be made to prevent a threatened miscarriage in the course of or after an attack of rubella, especially when the disease occurs in the early months. It is entirely up to the judgment of the attending physician to bring this to completion by surgical means. The medical profession is engaged in the prevention of disease, the preservation

born in 1942 with a congenital heart lesion, bilateral cataracts and complete deaf mutism, whose mother is said to have suffered a "sharp attack" of rubella six weeks before conception. Sweet¹⁰⁰ supplies the report of a woman who contracted rubella ten days before conception, the date of conception being fixed by the husband's three-day military leave. This pregnancy resulted in the birth of an infant that had bilateral cataracts, patent ductus arteriosus and hydrocephalus and lived only three months. The mother has since given birth to a perfectly normal child. In contrast are the 2 cases reported by Swan and Tostevin⁶⁸ in which rubella was contracted thirteen days and six days, respectively, before conception. This was figured out on the assumption that "ovulation occurs approximately fourteen days before the onset of the next menstrual cycle and that fertilization takes place within twenty-four to forty-eight hours of ovulation." It is interesting that in the first case a therapeutic abortion was carried out in view of the possibility that the child would be malformed. The specimen sent to the pathological laboratory consisted of fragments of tissue. Both eyes were intact, and further histopathological examination revealed no abnormality. The other patient went to term, and the child was normal.

TREATMENT

Aside from the problem of rubella in pregnancy, this disease is so relatively mild in the vast majority of cases that the natural recuperative powers of the body need no special help from the armamentarium of the physician. If fever is present bed rest appears to be indicated, unless the new notion of getting sick people out of bed captures the fancy of the modern doctor. Certainly, bed rest need not be enforced too strictly. One has but to be reminded that in another virus disease — namely, mumps — it has been clearly shown that the old notion of strict bed rest does not diminish the incidence of orchitis. It is highly improbable that complete rest in bed will diminish the rare complications of rubella. Most of the patients with mild cases do not stay in bed anyway and do perfectly well if they are permitted to be up and about. One must take into consideration the possibility that such a serum will be contaminated with infectious hepatitis. Gamma globulin, which has been proved to be effective after exposure to measles and ineffective after exposure to chicken pox, is as yet an untried weapon against rubella. Until a vaccine of modified rubella virus that will not give rise to a communicable form of the disease and yet will afford a permanent immunity has been perfected, the complicated problem of protecting pregnant mothers from contracting rubella will remain

TREATMENT OF THE PREGNANT MOTHER WHO CONTRACTS RUBELLA

It would be interesting to know whether pregnancy renders a woman more susceptible to rubella

Apparently, the manifestations of rubella in the pregnant woman are no severer than those in other persons, thus, there is no real direct danger from the virus to the mother herself. Once exposure has taken place and the incubation period has passed and the rubella eruption has reached the stage where the disease can be recognized, there is the possibility—in the early weeks of pregnancy, the probability—that the virus has gained access to the fetus. Evidence has been presented pointing to the susceptibility, which is particularly marked in the first two months of life, of certain fetal tissues to the virus of rubella. This premise presupposes that the virus would attack the fetal tissues as soon as it became active in the mother, if not sooner. If the virus has already combined with these fetal structures the question arises whether any number of protective antibodies contained in antisera administered to the mother would preclude serious damage to the fetus. By the time the disease is recognizable in the mother it is highly probable that the virus would already have accomplished serious injury to the more susceptible embryonic tissues, and that no amount of antiserum could offset the damage. The administration of such an antiserum in any of its present forms would leave one with the uncertainty of its efficacy.

Threatened Miscarriage

Whether or not antiserum has been administered, any signs of miscarriage ought to be welcomed, and I can see no justifiable reason for any attempts to avoid such a favorable event. There is nothing in the dictates of the medical profession or in the common law of English-speaking countries that instructs a physician to attempt to prevent a miscarriage in the face of the evidence that has been presented. To bring up the religious motive of preserving life at all costs is on a par with the superstition of the Hindu who will not kill a cobra that attacks his own child because the cobra is a sacred animal.

Of course, a human life is sacred. Yet, under certain circumstances, one may take a human life in self-defense, both in peace and in war. A nation at war expends the lives of its citizens. Physicians are not bound to preserve life at all costs. Nothing is gained by saving a life when agony and anguish lie ahead, whether in the death throes of cancer or in the future birth of a grossly deformed infant. Because human life is sacred, there are exceptions to preserving it at all costs and under all circumstances. Physicians are now faced with a new exception. No attempt should be made to prevent a threatened miscarriage in the course of or after an attack of rubella, especially when the disease occurs in the early months. It is entirely up to the judgment of the attending physician to bring this to completion by surgical means. The medical profession is engaged in the prevention of disease, the preservation

of life and the amelioration of suffering. The immediate problem does not come under the much discussed topic of legalizing euthanasia, which has to do with that praiseworthy function of making impending death comfortable. The problem presented by rubella in pregnancy deals with the prevention of suffering in its broadest sense.

Therapeutic Abortion and Its Medicolegal Aspects

The instigation of a therapeutic abortion is quite a different matter from allowing a threatened miscarriage to proceed and bringing it to completion by surgical means. The suggestion of terminating pregnancy after an attack of rubella was first introduced by Swan and his associates.⁷² In a subsequent article it was made clear that no legal grounds existed in Australia for the termination of pregnancy after rubella.⁷³ Furthermore, they gave as their expressed opinion that legislation to such an end might lead to its abuse. Albaugh⁶⁹ and Lynch,¹⁰³ in America, and Hughes,⁹⁶ in England, have urged that caution be used in the consideration of abortion. Fox and Bortin⁷⁰ found in the results of their Milwaukee investigations no justification for considering the termination of pregnancy. When one contemplates the mass of cumulated factual evidence presented in this paper the idea of therapeutic abortion cannot be pushed aside. Such abortions in 3 cases have already been reported in the medical literature.⁷⁴⁻¹⁰¹

In dealing with a diseased patient the physician uses every effort to remove all obstacles in the way of recovery. The word "recovery" must be construed to include the aftereffects of the disease. If a woman suffers an attack of rubella during the first months of pregnancy, the chances of her giving birth to a grossly deformed child are sufficient to warrant an abortion from the purely medical point of view to ensure complete recovery from the aftereffects of the disease. The law forbids physicians to perform an operation for that purpose.

According to the common law and the statutes in some states, it is illegal to terminate pregnancy except to save the life of the mother. For instance, therapeutic abortion is permitted in the case of a pregnant woman suffering from tuberculosis. This is done for the safety of the expectant mother. The consultation of a second physician—and usually the permission of the executive committee of the hospital—is required. After an attack of rubella the life of the mother is usually not endangered by a grossly deformed living fetus, only if the fetus develops a massive hydrocephalus can the life of the mother be said to be threatened. This is a relatively minimal danger. Nevertheless, such a possibility exists, even though remote, and could be seized on as a point in law, and possibilities are being dealt with. The woman with tuberculosis does not always succumb from carrying a child, but she is likely to do so. An attack of rubella in the early

months of pregnancy does not always result in serious malformations in the fetus, but it may do so. Such a possibility weighs heavily on the minds of the attending physician and the parents.

The purpose of terminating pregnancy is to prevent the birth of a deformed infant and to allow the mother to conceive again under more auspicious circumstances. The desire to accomplish this is irrelevant in the eyes of the law. From the legal point of view this desire is prompted by social reasons, which are not acceptable as valid grounds for abortion. These grounds are actually far more valid than the grounds in which abortion is usually sought, because the birth of a deformed child acts as a deterrent to future pregnancies. The birth of a deformed child as a result of rubella in no way prevents the future birth of normal babies. Nevertheless, in Australia, investigations showed that mothers of infants deformed by rubella refrained from having more children because of the fear of giving birth to another defective child or because the care of the defective child precluded their having any more children.⁷⁴

If the fetus dies the uterus may be emptied. There is no question here of destroying life. Consequently, the determination of a dead fetus warrants emptying of the uterus. It can always be argued that the presence of a macerated fetus could serve as a nidus for the Welch bacillus, so frequently inhabiting the intestinal tract of normal persons. Such a possibility, however, is remote. Ordinarily, a dead fetus offers no particular danger to the mother. The real question is how to determine the presence of a dead fetus in the early months of pregnancy. Failure of the uterus to grow is, of course, an indication that the fetus is dead. Consequently, if the attending obstetrician decides that the fetus is not living, he may empty the uterus. A consultation is indicated, to share responsibility, and the written permission of the expectant mother, as well as of the husband, should be obtained. Although the common law permits emptying of the uterus when the fetus is dead, the statutes on this whole subject vary in different states—for example, in Massachusetts, Maine, New York and Iowa.

The fundamental law regarding abortion lies in the Offense against the Persons Act of England. Any approach to this law as it relates to the pregnant woman who suffers an attack of rubella must be made with two possibilities in mind. The first, which has to do with a favorable interpretation of this law and the statutes that pertain to it, would permit an exception under these circumstances. The second, which concerns a change in the statutes, would grant permission to carry out abortion under the explicit circumstance of an attack of rubella. It is my purpose to show that a favorable interpretation has been rendered in relation to this subject in a court of law, and to bring out a pertinent bit of history regarding a law that was entirely changed.

The present status of the law regarding abortion in reference to rubella has been reviewed in an editorial in the *Lancet*. It is pointed out that abortion is a statutory felony under the Offense against the Persons Act. A later proviso was introduced as an amendment whereby no person should be guilty under this section if the act "was done in good faith for the purpose only of preserving the life of the mother." In 1938 Mr Justice Macnaghten, in charging a jury, suggested that this clause did not mean that the surgeon operates only if the life of the mother is in immediate danger. It was his opinion that this section of the law construed "reasonably" would protect the surgeon if in his best judgment the continuation of pregnancy would have led to the patient's becoming "a physical and mental wreck." The editorial continues as follows: "If a woman can be assured that her child is certain to be born with some terrible deficiency, it might well have the same effect." Actually, there is no more assurance that the child will be born with gross deformities as the result of rubella than there is that the woman with tuberculosis will die if allowed to continue her pregnancy. Nevertheless, if a woman is aware of the statistical evidence in her particular case regarding the period in her pregnancy when the attack of rubella took place, there can be no doubt that she would become "a mental and physical wreck" if the pregnancy were allowed to continue. Indeed, it could be said that in the end it might endanger her health as much as an attack of tuberculosis. Justice Macnaghten's opinion was rendered before anything was known of the dangers of rubella during pregnancy. A liberal interpretation of the law based on his construction would depend on the court and the sympathy of the jury. A closer interpretation of the law would stress the fact that the mother's life was not endangered by the attack of rubella, and that the surgical termination of pregnancy under such circumstances is therefore a felony. It is necessary to point out that conviction of such a felony brings a severe penalty, with fine, imprisonment and the loss of license to practice.

It was pointed out above that congenital deformities were at one time attributed to a witch casting a spell on a pregnant woman. Witchcraft was generally believed in, and there were laws regarding it. Those suspected were imprisoned, brought to trial and, on conviction, put to death. "Thou shalt not suffer a witch to live" (*Exodus 22:18*) is one of the laws of Moses. Jews, Roman Catholics and Protestants tortured, drowned, hanged and burned those suspected of practicing witchcraft.

Two hundred and fifty years ago the Salem witch trials rocked New England. The Scriptures were quoted by Puritan clergymen in support of these trials just as some clergymen today quote them as an argument against euthanasia. The presiding judge showed no mercy. Two physicians sat on the jury and contributed to the torture of the victims

by their cruel tests.¹⁰⁶ Those convicted were hanged. This went on for a year. The turning point came when the citizens of Boston pointed the finger of suspicion at the wife of the Royal Governor. Witchcraft was threatening those on high. The Governor now listened to the more enlightened members of the community. Clergymen, physicians, lawyers and merchants denounced these proceedings as cruel and barbarous, and the witch hunts came to a halt. A wave of repentance swept the populace, and prayers for forgiveness were offered in the churches. Horrible as it all was, the relative abruptness with which the trials stopped and the open repentance of the populace were unique in history. These New Englanders saw to it that this Mosaic law should never again occasion such injustice.

Forty-five years later the following law¹⁰⁷ enacted in the reign of James I was repealed in England:

All persons invoking any evil spirit, or consulting, covenanting with, entertaining, employing, feeding, or rewarding any evil spirit to be used in any witchcraft, sorcery, charm, or enchantment should be guilty of felony without benefit of clergy, and suffer death.

A new law prescribed that "No prosecution shall for the future be carried on against any person for conjuration, witchcraft, sorcery, or enchantment."¹⁰⁷

The last witch was burned in Spain in 1791 and in Poland in 1793 — a hundred years after the Salem trials.¹⁰⁸ The following quotation from a great scholar on witchcraft is instructive: "No jury, whether in a witch-trial or in any other case, can be more enlightened than the general run of the vicinage."¹⁰⁸ It has been estimated that in England thirty thousand persons suffered death from suspicion of witchcraft during a hundred and fifty years. By rough calculation based on the reports of the last five years there could have been at least an equal number of seriously deformed children born of mothers who had rubella in pregnancy during the past hundred and fifty years in English-speaking countries. New England has shown that, as soon as public opinion becomes sufficiently aroused, it can do away with laws that prove to be unjust. It is to be hoped that in this day and age a change in laws regarding abortion will not have to wait for the virus of rubella to attack the wives of our lawmakers.

Gregg's discovery that rubella early in pregnancy offers great danger of gross deformities in the child represents a distinct advance in medical knowledge. English-speaking countries can take pride in the many painstaking investigations that have enlarged the knowledge on this subject. The cumulated factual evidence presents a challenge to the existing law relative to therapeutic abortion. Although further investigations are needed to determine the accuracy of the evidence, it is certainly sufficient to warrant consideration of another amendment to grant permission for surgical interference after an attack of rubella. Such an amendment can be achieved only through enlightened public opinion.

The argument that the amendment to the law might be abused is, to use the words of the lawyers, "irrelevant, incompetent and immaterial," if untold mental suffering is thereby avoided and more births of healthy infants are achieved

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C CABOT

TRACY B MALLORY, M D, *Editor*

BENJAMIN CASTLEMAN, M D, *Associate Editor*

EDITH E PARRIS, *Assistant Editor*

CASE 33261

PRESENTATION OF CASE

A thirty-year-old man entered the hospital because of convulsive seizures.

He had been well until ten days before admission, when a severe headache had developed. On the next day there was an attack of slight twitching of the right upper lip, shortly afterward the patient became unconscious and had a generalized convulsive seizure. In the next ten hours he had two more attacks, which his wife described as beginning with a twitching of the right corner of the mouth followed rapidly by jerking movements of the right arm and a generalized convulsion. All episodes were preceded by a strange, unpleasant sensation of taste and smell and were followed by transitory nominal aphasia. Three days later the seizures recurred but were limited to the right side of the face and the right arm, without loss of consciousness, and were preceded by an aura of an unpleasant taste and odor. Five days before admission an attack was followed by persistent difficulty in naming objects, clumsiness of the right hand and "numbness" of the right hand and forearm and the right side of the face. The headache recurred intermittently. It was localized to the left temporal region if the patient lay on the left side, but it was severer and more generalized when he lay on the right side. When turning to the left side he felt as though "a bag of water" flowed over to the left side of his head. There had been no visual disturbance, nausea or vomiting.

The past history revealed no serious illnesses. The patient had been in an automobile accident five years previously, with momentary loss of consciousness.

Physical examination revealed a patient who was mentally alert but who had difficulty naming familiar objects. Speech was slurred and hesitant. The visual acuity, visual fields, fundi, pupils and ocular movements were normal. The right hand and arm were weak and clumsy. There was loss of position and gnostic sense in the right hand and a similar

although less marked motor and sensory deficit in the right lower extremity. The tongue deviated to the right. The remaining cranial nerves were normal. The arm, knee and ankle jerks were more active on the right than on the left. No pathologic reflexes were elicited.

The temperature, pulse and respirations were normal. The blood pressure was 135 systolic, 90 diastolic.

Examination of the blood showed a hemoglobin of 15 gm and a white-cell count of 7000. Urinalysis was negative. The initial spinal-fluid pressure was equivalent to 165 mm of water, with 1 lymphocyte per cubic millimeter and a total protein of 45 mg per 100 cc. The gold-sol test was negative. X-ray films of the chest were normal. An electroencephalogram showed a "generally rather ragged record, the raggedness most marked at and around the left parietal region." There were no well defined slow waves or indications of a well defined focus.

During the hospital stay, the patient complained occasionally of headache, which was relieved once by lumbar puncture. On the fifth hospital day he had a convulsive seizure involving the face, arm and leg on the right side. Burr holes were made, and on the following day a ventriculogram was taken. Only a small quantity of air was visible in the right lateral ventricle, which appeared to be displaced toward the right.

An operation was performed on the sixth hospital day.

DIFFERENTIAL DIAGNOSIS

DR JAMES B AYER: Three important points are not mentioned in the record. Was there a previous x-ray examination, and what did the plain film show? There is no note of a blood Wassermann or Hinton test. Was the patient right handed? Are the x-ray films of the later examination available?

DR STANLEY M WYMAN: These films were made after the burr holes.

DR AYER: Can any air be seen?

DR JOST MICHELSEN: This was a difficult ventriculogram. The patient had a seizure during the procedure, and only 8 cc of air could be injected.

DR AYER: Is that air in the area of the lateral ventricles?

DR WYMAN: I cannot be sure.

DR AYER: Assuming that the report is correct, that the right ventricle has some air in it, the left none, and that the right ventricle is displaced somewhat to the right, let us continue with the analysis. The first thing to ask ourselves is whether the patient had a gross anatomic intracranial lesion, because this must have been an intracranial disturbance. I think that we can say that this is so. The reason I ask that question is that once in a while focal convulsions appear in uremia and other conditions without gross pathologic changes. There

The argument that the amendment to the law might be abused is, to use the words of the lawyers, "irrelevant, incompetent and immaterial," if untold mental suffering is thereby avoided and more births of healthy infants are achieved

metastases In the case under discussion it failed to do so The evidence, I believe, points to a single lesion I see nothing to suggest a lesion elsewhere in the brain or in the nervous system, and I therefore believe that metastasis of any form is not likely Moreover, the man was only thirty years old, and the usual metastases occur in older people Two fairly common types of brain tumor that are seen in this location are glioma, which may well give exactly these symptoms, and meningioma Between the two there is not much to choose Frequently, meningioma is likely to grow from a petrous ridge or other dural attachment that shows roughening on x-ray study, which is not reported This is negative evidence that meningioma is less likely and suggests the more probable tumor to be glioma I should not care to say which type, but evidently it was rapidly growing and that is as far as I dare go

Could the lesion have been anything else? There is one condition that occurs rarely blocking of the foramen of Monro, leading to unilateral dilatation of the ventricle, which in turn causes tumor-like symptoms In this patient an attempt to inject air into the left ventricle seems to have failed, suggesting that it was not enlarged

I must therefore conclude that we are dealing with an expanding lesion in the left temporoparietal region, not a large one because of the fact that it was not causing an excessive increase in intracranial pressure as judged by the films of the skull, the headache and the spinal-fluid pressure I should favor an infiltrating glioma Certainly, a surgical operation is indicated

DR CHARLES S KUBIK This patient was operated on by Dr Michelsen, who will describe the pathological findings But before he does that, are there any suggestions regarding the diagnosis?

DR JAMES C WHITE The only comment I can make is that we have recently been over our brain tumors during the decade 1935-1944, and out of 640 cases in that period 160 patients had seizures, and in those that had seizures astrocytomas were the highest group — 50 per cent of 88 cases The meningiomas were the second greatest, occurring in 35 per cent The percentage in the Montreal Neurological Institute is even higher, but in considering Penfield's* series one must remember that anyone who has epilepsy in Canada goes to Montreal I therefore believe that his statistics of epilepsy associated with brain tumor are overweighted Two thirds of his patients with supratentorial tumors — and in this hospital, one third — had epilepsy In glioblastoma multiforme the incidence of seizure is 20 per cent and in metastatic carcinoma, 14 per cent In Montreal many patients with astrocytoma and meningioma had epileptic seizures

*Penfield W., and Erickson T C *Epilepsy and Cerebral Localization: A study of the mechanism, treatment and prevention of epileptic seizures* 1937 Springfield Illinois Charles C Thomas 1941

for months or years before operation, in this hospital the duration was only one month It is also of interest to note that convulsions accompanied many of our brain abscesses

CLINICAL DIAGNOSIS

Left frontoparietal brain tumor, probably glioma

DR AYER'S DIAGNOSIS

Expanding lesion, left temporoparietal region, probably glioma

ANATOMICAL DIAGNOSIS

Brain abscess

PATHOLOGICAL DISCUSSION

DR MICHELSEN Our reasoning was very much the same as Dr Ayer's First of all, we were not absolutely certain that we were dealing with an expanding lesion The ventriculogram was done to demonstrate the type of disease Although the filling was rather poor, we were satisfied, because there was definite displacement of the ventricular system The location of the lesion was quite obvious clinically The preoperative diagnosis was brain tumor We expected a glioma, and because of the rapid course of the disease we thought that this would probably be a glioblastoma multiforme A bone flap was turned down in the usual fashion A lesion was readily discovered on the surface, involving the lower portions of the anterior and posterior central gyri When we began to take a biopsy, pus escaped from a small opening On spreading the cortex, a typical abscess wall was found The pus contained an alpha-hemolytic streptococcus All of it was evacuated The dura was closed around the abscess A catheter drain was put into the cavity and brought out through an opening in the bone flap and scalp Postoperatively, the patient was treated with penicillin irrigations through the catheter and instillation of penicillin into the subarachnoid space via the lumbar route in addition to intramuscular injections He has been well since discharge from the hospital He had some seizures postoperatively and was therefore put on an anticonvulsive regime Needless to say, this must have been a metastatic abscess We searched for the primary focus of sepsis, but none was found We still do not know how this abscess got into the brain

DR KUBIK A small biopsy specimen consisted of brain tissue in which there was infiltration suggesting an acute process with polymorphonuclear leukocytes There was no fibroblastic capsule

DR MICHELSEN Because of the close proximity to important cortical centers we believed that excision of the capsule would not be advisable at that time

was no history that suggested uremia, and there was a persistence of Jacksonian seizures. I should therefore assume that this patient had an anatomic lesion somewhere within the skull.

What is the localization? The first thing to consider is the localizing symptoms given in the history. There were definitely Jacksonian seizures in the beginning, which frequently went over into general convulsions. These Jacksonian seizures indicate clinically definite localization in the left side of the brain. I think that we can be more accurate and say that the focus was low in the left temporo-parietal region, because the lips and the face were first involved. The aura of smell and taste is a definite sign of irritation of the hippocampal region. The headache was primarily on the left side, that is not, of course, a dependable sign for localization, but when it agrees with other things, the headache is often in fairly close proximity to the lesion.

The next symptom to comment on is the aphasia. From the clinical point of view aphasia is a localizing symptom of considerable value. Presumably this man was right handed, and the left side of the brain is therefore indicated. There is no long description of the aphasia, but the record states that it was "nominal." There was also slurring of the speech. That was probably something else and on the motor side of the paresis. Aphasia, primarily nominal, is characteristically seen in lesions of the temporal lobe. There are therefore a good many symptoms and signs on the clinical side alone indicating a lesion that could have been covered roughly by the palm of the hand and was low in the parietal region and primarily motor—although with a sensory overflow after an attack, since it is stated that the patient did not know where things were in his hand, and the aphasia and the aura point to the same region. The lesion may have extended farther, but I prefer to think that the later disturbance was an overflow from pressure or following a seizure and that the lesion itself did not involve the whole parietal region.

The pneumogram is not so conclusive as I thought it would be from the description, but no doubt it is true that there was some displacement of the brain to the right. I do not see how we can escape the conclusion that this was an anatomic lesion of considerable size in the region spoken of and confirmed more or less by the pneumogram. The x-ray films of the skull itself are not mentioned, but I think that they were essentially normal. Is that correct?

DR MICHELSEN: Yes.

DR AYER: What are the etiologic possibilities for such an expanding lesion?

The first group of conditions includes tumors, which are the most frequent in such cases. I shall take them up in a moment. The next is an abscess. Could this have been an abscess? That is not a rare cause of these symptoms, with the exception

perhaps of the aura of smell and taste, which is unusual in abscess, because probably 9 out of 10 cases come from the ear, which is not mentioned as having been abnormal. There was no discharge from the ear, the patient did not have chronic otitis media. Such abscesses invade the temporal lobe much farther posteriorly and do not give the picture that this patient presented. I am against the diagnosis of abscess because there was no chronic ear condition, because of the presence and importance of the aura of taste and smell and because of the spinal fluid, which showed no cells and which should have shown cells if an abscess had been present. Cysts are rare, especially hydatid cysts. No one has mentioned the liver in this case, and I think that if this had been a cyst the liver would have been enlarged. I have no further comment on cysts.

Granulomas should be considered. The granulomas we have seen have usually been in the upper part of the brain. I do not recall seeing any in this particular location, although I do not know why they should not occur there. The blood Wassermann and Hinton tests are not recorded, but I assume that they were negative. There is nothing in the history and nothing in the examination otherwise to indicate syphilis.

Could this have been a collection of blood? Two types could cause these symptoms. In acute hemorrhage there is sometimes an intracerebral blood clot, which acts in this way. There was nothing in the history to suggest it. There was no blood in the spinal fluid, which there might well have been, and the patient would surely have been sicker than he was, for he was normal between the intervals of convulsions. This I should not expect with an intracerebral collection of blood. The most frequent collection of blood, however, is extracerebral, usually subdural hematoma, which is a bugbear that we often meet. There is a note, which I think is a red herring, that the patient had sustained an injury to the head five years previously, it was apparently not severe but could account for the later development of subdural hematoma. In my experience, however, the mechanism of growth of subdural hematoma should produce these symptoms within a year, usually much sooner, with a lucid interval for months prior to development of symptoms. Five years is long enough to make it most unlikely that subdural hematoma exists. Moreover, these subdural collections are almost always higher in the parietal area. I therefore believe that a subdural collection of blood is unlikely.

The most frequent cause of these expanding lesions is a tumor. There is nothing in favor of metastasis that I can see. Metastatic tumor may be single in the brain but is usually multiple. In a large percentage of cases the lung also shows

developed. These had been relieved, and he was again well until four days before admission, when he noted the onset of jaundice. The important physical findings were that the patient was jaundiced and that he had a large liver.

It would be helpful to know what the region of the prostate felt like, but the previous operative procedure made this impossible. The problem resolves itself into the differentiation of the causes of jaundice and we turn to the laboratory for aid. A white-cell count of 15,000 is reported. This is consistent with the finding in obstructive jaundice or intrahepatic disease with considerable destruction of parenchymal tissue. The findings of bile in the urine and chalk-white stools, together with a blood cholesterol of 403 mg and an alkaline phosphatase of 70 units per 100 cc, point to an obstructive jaundice. The alkaline phosphatase is usually elevated in obstructive jaundice and is not generally high in cases of intrahepatic liver disease without an obstructive component. On the other hand the highest phosphatase I have ever seen was in a patient with biliary cirrhosis, in whom no definite obstruction had ever been demonstrated.

The urinary symptoms and findings were obviously due to an obstruction in the urinary tract, with superimposed infection. From the evidence at hand this obstruction was at the base of the bladder and the region of the prostate, possibly involving the right ureteral orifice.

The x-ray films provide little definite information. The upper gastrointestinal tract appears to have been essentially normal except for some deformity of the duodenal cap, which may or may not represent an old ulcer. I do not see anything in the region of the head of the pancreas. The mass described in the lower abdomen is in the region of the bladder. This could be due to a bladder full of urine, and I should like to know whether or not the clamp that is visible in the region of the catheter was attached to the catheter or not. I am inclined to believe that the mass represents something more than a full bladder because of the previously mentioned urinary symptoms and findings.

If the report of the physical examination is correct, this man had a tremendously large liver, and on this basis alone one suspects something more than primary parenchymal disease in that organ. In discussing the possibilities I think that it might be said that although biliary cirrhosis cannot be ruled out, it is not likely if the findings of a mass in the lower abdomen and the urinary symptoms are to be fitted into the same diagnosis. In any event one possibility is biliary cirrhosis and benign prostatic hypertrophy, with hydronephrosis on the right and superimposed pyelonephritis. A second, likelier diagnosis is a malignant tumor, such as carcinoma of the bladder, with metastases to the liver and to the extrahepatic biliary tract. A third

possibility is that this patient had metastases from the original lesion into the lymph nodes in the region of the base of the bladder, causing bladder-neck obstruction and obstruction in the region of the right ureter, and also metastatic spread to the liver. Metastasis to the liver from primary carcinoma of the rectum is usually a late manifestation, although it can occur early. If this patient were from Egypt rather than Bermuda one would have to consider *Schistosoma haematobium* as a cause of cancer of the bladder, with metastatic spread to the liver. This, however, is extremely unlikely. The vague digestive disturbances such as postprandial distention are, I think, perfectly consistent with the degree of liver involvement. The fact, which is mentioned twice, that there was some delay in recurrence from the colostomy enemas does not impress me in view of the negative examination after a barium enema.

In conclusion, I believe that this patient had a malignant tumor with metastases to the liver. I believe that the jaundice was partially due to obstruction of the major radicles of the biliary tree by metastases. This may have been at the porta hepatis, or it may have involved the common duct. The size of the liver suggests that it was full of metastases, and there may have been enough obstruction of the bile canaliculi due to metastases to cause the jaundice. I should not expect white stools however, unless there was obstruction of the hepatic or common bile duct. I suppose that primary carcinoma of the liver could have been present, with the urinary findings on an entirely separate basis. I do not understand why this case is being discussed here today if this were a simple case of metastases to the pelvic floor and to the liver from the original adenocarcinoma. Therefore, I put as my first possibility primary carcinoma of the bladder causing bladder-neck obstruction and interference with drainage of the right ureter, with secondary obstruction in the bladder and kidney and with metastases to the liver and probably elsewhere.

DR BENJAMIN CASTLEMAN: The first operation performed at this admission was a peritoneoscopy by Dr Edward B. Benedict. He found a markedly enlarged liver, whose surface was mottled, gravis green and smooth. No carcinomatous implants were seen. The gall bladder was dilated to three or four times the normal size. The rest of the peritoneal cavity, including the pelvis, was inspected by putting the patient in the Trendelenburg position. A biopsy of the liver was taken.

Have you any comment, Dr Ellis?

DR ELLIS: This is further evidence for obstruction of the common duct and against interference with the manufacture and flow of bile into the gall bladder. There may have been a common-duct stone, but there were few symptoms of it other than

DR KUBIK Occasionally, we see an abscess like this in which no focus of infection can be found. Most cerebral abscesses are a result of sinus infection, otitis media or chronic suppuration in the lungs. We have had two or three fatal cases in which the sinuses, ears and lungs appeared to be normal and in which the source of the infection could not be determined.

DR WHITE Has this patient had postoperative seizures? In our experience a great many patients with abscesses have seizures both in the acute stage and after operation.

DR MICHELSEN Yes, he had some, but we put him on an anticonvulsion regime, soon after the operation, and I suppose that it worked all right.

DR AYER I do not see how the spinal fluid could have been normal. Was it examined carefully?

DR MICHELSEN The fluid was examined four times, on one occasion I examined it myself, and only 1 leukocyte per cubic millimeter was found.

DR AYER That is unusual in abscess.

DR MICHELSEN Of course, the duration was short — only ten days.

DR AYER Yes, that often happens in tumor.

DR KUBIK In a case of glioblastoma some time ago the entire duration of symptoms was only twelve days. Such a rapid course is rare but does occur occasionally. We have had a few other cases of abscess without cells in the spinal fluid, but those, I believe, were old, chronic abscesses. One would expect cells in an acute case such as this.

CASE 33262

PRESENTATION OF CASE

A seventy-one-year-old Bermudian Negro entered the hospital because of jaundice.

Two and a half years before admission the patient had undergone a combined abdominoperineal resection for an adenocarcinoma (Grade II) of the rectum. On microscopical examination the regional lymph nodes contained no tumor. After operation, the patient was followed in the Out Patient Department periodically for over two years. The colostomy functioned well, and he had no complaints except slight dysuria, narrowing of the urinary stream and dribbling and nocturia. Four months before admission he had a two-week episode of pain in the right flank and pyuria. After catheterization he failed to return to the clinic. Four days before entry the patient's sister noticed that the eyes were yellow. In retrospect he recalled that the urine had left greenish stains on the underclothes for several months. The stools had been lighter than formerly but were still slightly brown or yellow. The appetite was poor, and the patient had been troubled with distention and flatulence after eating. Later he noted that the daily enema returns from the colostomy were delayed over periods of two hours.

There had been no abdominal pain, nausea, vomiting or headache. There was no history of itching, bleeding or drug intake.

Physical examination disclosed generalized vitiligo. The pale areas and the scleras were yellow. The liver border extended 6 cm. below the costal margin, the upper limit of dullness being at the fourth rib. Neither the gall bladder nor the spleen could be palpated. The colostomy appeared normal. A rather large, reducible, direct hernia protruded in the left inguinal region. The perineum had healed.

The temperature was 98.8°F, the pulse 70, and the respirations 20. The blood pressure was 120 systolic, 85 diastolic.

Examination of the blood revealed a hemoglobin of 13 gm. and a white-cell count of 15,000, with 72 per cent neutrophils. The urine gave a +++ test for bile and a ++ test for albumin, and the sediment contained 50 white cells per high-power field. The stools were chalk white and semiformed. The van den Bergh reaction was 16.8 mg. per 100 cc. direct, and 24.8 mg. indirect. The cholesterol was 403, the phosphorus 2.8, the nonprotein nitrogen 36 and the calcium 8.0 mg. per 100 cc. The alkaline phosphatase was 70 units per 100 cc. The total protein was 5.3 gm. per 100 cc., with 3.1 gm. of albumin and 2.2 gm. of globulin. The prothrombin time was 25 seconds (normal, 17 to 19 seconds).

X-ray films of the chest were normal. In a gastrointestinal series the duodenal cap appeared markedly narrowed at the tips. There was a slight pressure defect at the point where the superior mesenteric vessels crossed the duodenum, but no definite mass was visualized.

In the hospital the patient's condition remained about the same, although the jaundice increased slightly. Filiform catheters were passed through an obstructed prostatic urethra with difficulty, and constant drainage was instituted. He continued to have crampy postprandial distention, and it took two hours for the daily enema to return. A barium enema passed through the colon into the terminal ileum without evidence of obstruction. A loop of ileum descended into the left inguinal region. Above and medial to this loop was a defect caused by pressure of a soft-tissue mass that was not clearly visualized and lay in the region of the prostate or of the previous operative site in the area of the rectum. This mass measured approximately 7 cm. in diameter.

An operation was performed on the thirteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR DANIEL S. ELLIS In summary, this patient had undergone an abdominoperineal resection for adenocarcinoma of the rectum two and a half years before admission. He had been well until four months before admission, when urinary symptoms

THE BOSTON DISPENSARY

THE Boston Dispensary in March of this year, with Surgeon General Parran as guest speaker, celebrated a little tardily its one hundred and fiftieth anniversary. This sesquicentennial celebration—the half century is still an important landmark in our young country—serves to recall certain events in the history of the Dispensary, as well as its present needs.

The Dispensary, we are reminded, came officially into being at the Boston Chamber of Commerce on September 11, 1796, with the acceptance by a group of citizens of a report from Dr. Oliver Smith and Mr. William Tudor providing rules and regulations for the proposed institution. The third such dispensary in the country and today the only

survivor of the three, the Boston Dispensary was also the first medical charity in New England.

Coming into existence less than twenty years after the signing of the Declaration of Independence, the Dispensary followed by fifteen years the foundation of the Massachusetts Medical Society—the first state society in the country with a continuous existence—and antedated by sixteen years the establishment of the *New England Journal of Medicine and Surgery* and by twenty-five years the opening of the doors of the Massachusetts General Hospital.

Thomas Bartlett's apothecary shop on Corn Hill became the first headquarters of the organization and here hung its first signboard, bearing the picture of the Good Samaritan to represent its functions. Its three main principles were embodied in the report submitted by Dr. Smith and Mr. Tudor:

The sick, without being pained by a separation from their families, may be attended and relieved in their own houses.

The sick can, in this way, be assisted at a less expense to the public than in any hospital.

Those who have seen better days may be comforted without being humiliated, and all the poor receive the benefits of a charity, the more refined as it is the more secret.

The services of the Dispensary increased as the town and the Commonwealth prospered. In 1801 it was incorporated, twenty years later, on the principle that "the moral effect of a clean skin is often more potent in the treatment of ailments than the administration of drugs," it procured a bathtub to be located conveniently "in some central place." In 1856 its clinic for ambulatory patients was opened, in 1873 the country's first clinic for syphilis and the first dental clinic, and in 1899 the first pulmonary clinic.

The Boston Floating Hospital, finally grounded, was established on land in conjunction with the Dispensary in 1929, and at the time of this union plans for the New England Medical Center, to include Tufts College Medical and Dental schools were formed. The Joseph H. Pratt Diagnostic Hospital was added in 1938.

Like all the charitable institutions that have carried on through the war years without expansion, the Dispensary is now in need of funds to

jaundice The large liver still puzzles me, and I think that it was larger than that usually found in biliary cirrhosis I am probably wrong, but I shall stick to the original diagnosis of metastasis to the liver, with tumor obstructing the common duct In the absence of positive peritoneoscopic findings of tumor in the pelvis the chances favor metastases from the original carcinoma of the rectum, even after two and a half years

DR WADE VOLWILER I saw this patient after the peritoneoscopy and believed that the distended gall bladder, the elevated cholesterol, the high alkaline phosphatase and the absence of splenomegaly indicated common-duct obstruction by tumor My best bet was lymph-node metastases from the carcinoma of the rectum I also believed that there were hepatic metastases not visible by peritoneoscopy

CLINICAL DIAGNOSIS

Carcinoma of head of pancreas

DR ELLIS'S DIAGNOSIS

Metastatic carcinoma of liver and lymph nodes around extrahepatic biliary ducts from carcinoma of bladder or from carcinoma of rectum

ANATOMICAL DIAGNOSIS

Metastatic adenocarcinoma of lymph nodes around bile ducts from previously resected adenocarcinoma of rectum

PATHOLOGICAL DISCUSSION

DR CASTLEMAN The liver biopsy showed an extreme grade of bile stasis and obstructive cirrhosis, but no evidence of carcinoma

Following this report the patient was explored with a preoperative diagnosis of carcinoma of the head of the pancreas, this diagnosis being chosen probably because of the slight pressure on the duodenum visualized on the x-ray films At operation the liver was large and slightly granular but showed no evidence of carcinoma The gall bladder was tremendously dilated, measuring about 10 cm in diameter Surrounding and compressing the extrahepatic bile ducts were nodules of tumor that proved microscopically to be adenocarcinoma characteristic of the type seen in the colon

continue the fulfillment of its destiny. Other charities may have an equal claim on the generosity of the public, surely none can have a greater

REFSUM'S DISEASE

A FAMILIAL disease, not hitherto described, has recently been reported from Norway.* The syndrome was observed in two Norwegian families, not related to each other. In one, a brother and a sister were affected, in the other, two sisters and their cousin. The chief symptoms were hemeralopia (retinitis pigmentosa), polyneuritis, ataxia and other cerebellar manifestations. Both patients in the first family died suddenly of respiratory paralysis. The pathologic changes were limited to the brain, with degeneration in the lipid content and pigment anomalies. The lesions closely resembled those found in Niemann-Pick disease and in familial amaurotic idiocy.

The first clinical symptoms were limitation of the fields of vision and hemeralopia. These complaints often preceded difficulty in walking, due to the ataxia, by many years. Paresthesias were most marked in the hands and feet. In some cases the pain was said to be "burning" or "shooting" in character. No case showed mental manifestations. The ataxia was of the cerebellar type, and other vague cerebellar symptoms were occasionally present. The cerebrospinal fluids contained large amounts of protein, without a corresponding increase in cells, findings somewhat similar to those in the Guillain-Barré syndrome. Three patients had sinus tachycardia by electrocardiographic examination. Others had abnormalities of the pupils, deafness or epiphyseal dysplasia. The syndrome was considered hereditary, probably of a simple recessive type. When large amounts of vitamins were given, at least one patient showed objective improvement.

MASSACHUSETTS MEDICAL SOCIETY

ANNUAL REGISTRATION IN INDIANA

Indiana has recently passed a law requiring annual registration of physicians, which becomes effective on July 1. The fee for those who are nonresidents is \$10.00, and the licensee must register before August

31. Since failure to register results in automatic cancellation of the certificate, all who hold Indiana licenses and wish to retain them should obtain application for registration from the State Board of Medical Registration and Examination, K of P Building, Indianapolis 4.

JOSEPH GARLAND, Secretary

ANNUAL GOLF TOURNAMENT

The winners at the annual golf tournament of the Massachusetts Medical Society, which was held at the Woodland Golf Club on the afternoon of May 15, were as follows: low gross, R. J. Nugent, second gross, M. Sargent, low net, A. D. Crowell, second low net, G. Quigley.

MISCELLANY

NOTE

Dr. Duncan E. Reid will become William Lambert Rich, son Professor of Obstetrics at the Harvard Medical School and obstetrician-in-chief to the Boston Lying-in Hospital July 1. He succeeds Dr. Frederick C. Irving, who resigns both positions as of December 31, 1946. Dr. Reid has served continuously on the staff of the Lying-in Hospital since 1911 and joined the staff of the Harvard Medical School in 1918. Born in Burr Oak, Iowa, on December 22, 1905, he graduated from Ripon College in 1927. He received his medical degree from Northwestern University in 1932 and served as an intern and resident at the Passavant Memorial and St. Luke's hospitals of that city before coming to Boston.

CORRESPONDENCE

LABORATORY TRAINING IN PARASITOLOGY

To the Editor: The *Journal* is to be congratulated on excellent editorial, "Diagnosis of Amebiasis by Stool Examination," that appeared in the April 24 issue. It demonstrates a thorough understanding of the laboratory problem involved in this difficult examination. It agrees closely with what we believe and teach in the Parasitology Branch, Laboratory Division of the Public Health Service. In the editorial mentions "the need for improved training of hospital laboratory technicians in the performance of examinations," you may be interested in knowing about our laboratory training program.

Since October, 1945, we have been conducting a six-week course in the laboratory diagnosis of parasitic diseases, the sessions having been completed. This course is open to all grades of laboratory personnel, and although at the present time our first responsibility is to the laboratories of state and local health departments, we are glad to accept persons from private hospitals and laboratories as vacancies occur. There is no tuition or laboratory fee, but travel and living expenses must be paid for by the individual or his employer.

In addition to the parasitology course, the Laboratory Division offers an extension service of parasitologic material. This service involves monthly shipments of specimens that are numbered and accompanied by a key to the correct diagnosis. This service is also open to state and local health departments and to the students who have attended our course in Atlanta.
